

PROCEEDINGS OF THE

# *10<sup>th</sup>* INTERNATIONAL **MODELICA** CONFERENCE

March 10-12, 2014  
Lund, Sweden  
[www.modelica.org](http://www.modelica.org)

EDITORS: HUBERTUS TUMMESCHEIT AND KARL-ERIK ÅRZÉN

*Modelon*

*m*  
**MODELICA**

The Conference is organized by Modelon in collaboration with the Linnaeus center LCCC at Lund University in cooperation with the Modelica Association.

**Proceedings of the 10<sup>th</sup> International Modelica Conference**  
Lund, Sweden, March 10-12, 2014

**Editors:**

Dr. Hubertus Tummescheit and Prof. Karl-Erik Årzén

**Published by:**

Modelica Association and Linköping University Electronic Press

ISBN: 978-91-7519-380-9

Series: Linköping Electronic Conference Proceedings, No 96

ISSN: 1650-3686

eISSN: 1650-3740

DOI: <http://dx.doi.org/10.3384/ecp14096>

**Organized by:**

Modelica Association

and

Modelon AB

c/o PELAB, Linköpings Univ.

IDEON Science Park

SE-581 83 Linköping

## Welcome

The 10<sup>th</sup> International Modelica Conference is the main event for our community. Users, library developers, tool vendors, and language designers will gather to share their knowledge and learn about the latest scientific and industrial progress related to Modelica and FMI (Functional Mockup Interface).

This 10<sup>th</sup> milestone conference returns to Lund, where the first event took place in 2000. Since then, Modelica has matured from an idea among a small number of dedicated enthusiasts to a widely accepted standard language for the modeling and simulation of cyber-physical systems. Modelica is now used in many industries including automotive, energy and process, aerospace, and industrial equipment. Modelica has even been tapped for one-of-a-kind systems engineering designs such as the ESS (European Spallation Source) which is currently being built nearby in Lund. Modelica is the language of choice for modeling and simulation of complex system interactions.

The addition of the FMI standard to the project portfolio under the stewardship of the Modelica Association has greatly strengthened Modelica. FMI provides a complementary standard that enables deployment of high quality models to a larger number of engineers working with system design and verification.

Conference highlights:

- 2 Keynote speeches
- 114 papers in 5 parallel tracks
- 23 posters
- 6 tutorials
- 5 libraries for the Modelica Library Award
- 6 vendor sessions presenting the latest Modelica and FMI tools
- A fully booked exhibition area featuring 18 exhibitors
- Electronic proceedings including all papers and some associated Modelica libraries and models

The conference also presents new initiatives from the Modelica Association. Since the last conference, there has been a major effort to improve the standards compliance process for the Modelica language, the Modelica Libraries developed by the Modelica association, and the FMI standard.

- The latest Modelica Standard Library release (MSL 3.2.1) has been enhanced and modified to be fully compliant with the Modelica Language Standards version 3.2 rev2, and is now solely based on open source code under the Modelica License version 2.0.
- MSL 3.2.1 has also been improved to significantly simplify comparisons of simulations of the same model across multiple Modelica environments. Tools to support such comparisons are now available through the Modelica Association.
- The Modelica language version 3.2rev 2 fixed many ambiguities in the specification.
- A Modelica Compliance Test Library has been carefully designed and implemented to verify that a Modelica tool is compliant to the Modelica specification. It has been tested with many tools, with agreed-upon reference results.
- A set of FMI Cross Check Rules was established in July 2013 and has been used by many vendors to verify tool quality and interoperability. All results are publically presented in a dynamic, online, tabular reference.

These combined efforts have helped to increase the industrial acceptance, commitment to, and use of Modelica and FMI as central standards for analytic model based systems engineering.

Finally, we want to acknowledge the support we received from the program board and program committee. Special thanks to this year's organizers, the Modelica Association, Modelon AB, and Amelie Rönngård from Anagram. Last but not least, let us thank all authors for their contributions to this conference.

We wish all participants an enjoyable and successful conference.

West Hartford and Lund, February 10<sup>th</sup> 2014

Hubertus Tummescheit and Karl-Erik Årzén

## Program Committee

### Program Chairs

Dr. Hubertus Tummescheit, Modelon Inc., USA  
Prof. Karl-Erik Årzén, Lund University, Sweden

### Program Board

Dr. Hilding Elmqvist, Dassault Systèmes, Lund, Sweden  
Prof. Peter Fritzson, Linköping University, Sweden  
Prof. Martin Otter, DLR, Germany  
Dr. Michael Tiller, Xogeny, Michigan, USA

### Program Committee

Dr. Johan Åkesson, Modelon AB, Lund, Sweden  
Prof. Karl-Erik Årzén, Lund University, Lund, Sweden  
Prof. Bernhard Bachmann, Univ. Applied Sciences Bielefeld, Bielefeld, Germany  
Dr. John Batteh, Modelon Inc., Ann Arbor, USA  
Dr. Albert Benveniste, INRIA, Rennes, France  
Christian Bertsch, Robert Bosch GmbH, Stuttgart, Germany  
Volker Beuter, VI-grade GmbH, Marburg, Germany  
Torsten Blochwitz, ITI GmbH, Dresden, Germany  
Dr. Scott Bortoff, MERL Cambridge, USA  
Daniel Bouskela, EDF R&D, Paris, France  
Dr. David Broman, University of California, Berkeley, USA  
Dr. Dan Burns, MERL, Cambridge, USA  
Prof. Francesco Casella, Politecnico di Milano, Milano, Italy  
Prof. François E. Cellier, ETH Zürich, Zürich, Switzerland  
Dr. Christoph Clauß, Fraunhofer IIS EAS, Dresden, Germany  
Mike Dempsey, Claytex Services Ltd, UK  
Dr. Bernard Dion, Esterelle Technologies, Paris, France  
Dr. Hilding Elmqvist, Dassault Systèmes, Lund, Sweden  
Dr. Hosam Fathy, PennState, University Park, PA, USA  
Prof. Gianni Ferretti, Politecnico di Milano, Italy  
Dr. Rüdiger Franke, ABB AG, Mannheim, Germany  
Prof. Peter Fritzson, Linköping University, Sweden  
Dr. Degang Fu, United Technologies Research Lab, Shanghai, China  
Dr. Rui Gao, Dassault Systèmes Japan, Tokyo, Japan  
Prof. Manfred Hajek, TU Munich, Munich, Germany  
Peter Harman, CyDesign, Coventry, United Kingdom  
Dr. Andreas Heckmann, DLR, Munich, Germany  
Anton Haumer, Technical consultant, St. Andrae-Woerden, Austria  
Dr. Dan Henriksson, Dassault Systèmes, Lund, Sweden  
Prof. Bengt Jacobson, Chalmers Technical University, Gothenburg, Sweden  
Bill Janssen, PARC, Palo Alto, USA  
Jochen Köhler, ZF AG, Friedrichshafen, Germany  
Dr. Christian Kral, Vienna, Austria  
Imke Lisa Krüger, Modelon GmbH, Hamburg, Germany  
Dr. Chris Laughman, MERL, Cambridge, USA  
Prof. Alberto Leva, Politecnico di Milano, Italy  
Kilian Link, Siemens AG, Erlangen, Germany  
Prof. Edward Lee, UC Berkeley, USA  
Dr. Sven-Erik Mattsson, Dassault Systèmes, Lund, Sweden  
Kristin Majetta, Fraunhofer IIS, Dresden, Germany  
Dr. Jakob Mauss, QTronic GmbH, Berlin, Germany  
Dr. Lars Mikelsons, Bosch-Rexroth GmbH, Lohr am Main, Germany  
Prof. Dr.-Ing. Dirk Müller, Aachen, Germany  
Ramine Nikoukhah, Altair Development France, Antony, France  
Prof. Mattias Nyberg, Scania AB, Södertälje, Sweden

Dr. Hans Olsson, Dassault Systèmes, Lund, Sweden  
Prof. Martin Otter, DLR, Germany  
Prof. Peter Pepper, TU Berlin, Berlin, Germany  
Dr. Nicolas Pernet, IFP Energies nouvelles, Rueil-Malmaison, France  
Dr. Adrian Pop, Linköping University, Sweden  
Johan Rhodin, Wolfram Research, Illinois, USA  
Dr. Michael Sasena, LMS, , Ann Arbor, USA  
Prof. Gerhard Schmitz, Technical University Hamburg-Harburg, Germany  
Dr. Clemens Schlegel, Schlegel Simulation, Munich, Germany  
Dr. Peter Schneider, Fraunhofer IIS EAS, Dresden, Germany  
Dr. David Smith, Synopsis, Oregon, USA  
Dr. Wilhelm Tegethoff, TLK-Thermo GmbH and TU Braunschweig, Germany  
Dr. Ed Tate, Exa, Livonia, USA  
Eric Thomas, Dassault-Aviation, Paris, France  
Dr. Michael Tiller, Xogeny, Michigan, USA  
Dr. Jakub Tobolar, DLR, Munich, Germany  
Dr. Hubertus Tummescheit, Modelon Inc., West Hartford, USA  
Dr. Andreas Uhlig, ITI GmbH, Dresden, Germany  
Prof. Alfonso Urquía, UNED, Spain  
Dr. Subbarao Varigonda, Cummins, Columbus, USA  
Dr. Stéphane Velut, Lund, Sweden  
Stefan Vorkoetter, MapleSoft, Waterloo, Canada  
Dr. Michael Wetter, LBNL, Berkeley, USA  
Dr. Dirk Zimmer, DLR, Germany

**Local organizers:**

Magnus Gäfvert, Modelon AB  
Jonas Eborn, Modelon AB  
Eva Westin, LCCC, Lund University  
Amelie Rönngard, Anagram

# Contents

<b>Keynote</b>	<b>17</b>
Modelica Evolution - From My Perspective . . . . .	17
<b>Session 1A: FMI 1</b>	<b>27</b>
The Functional Mockup Interface - seen from an industrial perspective . . . . .	27
An FMI-Based Tool for Robust Design of Dynamical Systems . . . . .	35
Simulating Rhapsody SysML Blocks in Hybrid Models with FMI . . . . .	43
Nonlinear State Estimation with an Extended FMI 2.0 Co-Simulation Interface . . . . .	53
<b>Session 1B: Automotive Applications 1</b>	<b>63</b>
Model-based Development of Future Small EVs using Modelica . . . . .	63
Modeling of an Electric Axle Drive with Modelica: A Study of Electric Active Dynamics . . . . .	71
Utilizing Object-Oriented Modeling Techniques for Composition of Operational Strategies for Electrified Vehicles . . . . .	79
Thermal shock testing for Engines in Dymola . . . . .	89
<b>Session 1C: Building Energy Applications 1</b>	<b>97</b>
Model-Based Design of Integrative Energy Concepts for Building Quarters using Modelica . . . . .	97
Enhancement of the building simulation software TRNSYS by coupling to the VEPZO model programmed in Modelica . . . . .	107
The Modelica Thermal Model Generation Tool for Automated Creation of a Coupled Airflow, Radiation Model and Wall Model in Modelica . . . . .	115
Modelling long-wave radiation heat exchange for thermal network building simulations at urban scale using Modelica . . . . .	125
<b>Session 1D: Electro-Magnetic Models and Libraries 1</b>	<b>135</b>
Extension of the FundamentalWave Library towards Multi Phase Electric Machine Models . . . . .	135
New Multi Phase Quasi Static Fundamental Wave Electric Machine Models for High Performance Simulations . . . . .	145
The New EDrives Library: A Modular Tool for Engineering of Electric Drives . . . . .	155
Modelica Models for Magnetic Hysteresis, Materials and Transformers . . . . .	165
<b>Session 1E: Modelica Language &amp; Compiler Implementation</b>	<b>173</b>
Custom Annotations: Handling Meta-Information in Modelica . . . . .	173
Modelica extensions for Multi-Mode DAE Systems . . . . .	183
Integrated Debugging of Equation-Based Models . . . . .	195
Making Modelica Applicable for Formal Methods . . . . .	205
<b>Session 2A: FMI 2</b>	<b>213</b>
Implementing stabilized co-simulation of strongly coupled systems using the Functional Mock-up Interface 2.0 . . . . .	213
Context-based polynomial extrapolation and slackened synchronization for fast multi-core simulation using FMI . . . . .	225
Model-Based Integration Platform for FMI Co-Simulation and Heterogeneous Simulations of Cyber-Physical Systems . . . . .	235
Adapting Functional Mockup Units for HLA-compliant Distributed Simulation . . . . .	247
<b>Session 2B: Automotive Applications 2</b>	<b>259</b>
Transmission Modeling in Modelica: A consistent approach for several software development platforms	259
Vectorized single-track model in Modelica for articulated vehicles with arbitrary number of units and axles . . . . .	265
Multibody Model of a Motorbike with a Flexible Swingarm . . . . .	273
Modelling and parameter identification of a semi-active vehicle damper . . . . .	283

<b>Session 2C: Building Energy Applications 2</b>	<b>293</b>
The Modelica HouseModels Library: Presentation and Evaluation of a Room Model with the ASHRAE Standard 140 . . . . .	293
Modelica Library for Building and Low-Voltage Electrical AC and DC Grid Modeling . . . . .	301
Tool coupling for the design and operation of building energy and control systems based on the Functional Mock-up Interface standard . . . . .	311
Coupling occupant behaviour with a building energy model - A FMI application . . . . .	321
<b>Session 2D: Electro-Magnetic Models and Libraries 2</b>	<b>327</b>
Phenomenological Li ion battery modelling in Dymola . . . . .	327
A Modelica Based Lithium Ion Battery Model . . . . .	335
Behavioral Modeling of Power Semiconductors in Modelica . . . . .	343
<b>Session 2E: Modelica Tools 1</b>	<b>353</b>
Verification and Design Exploration through Meta Tool Integration with OpenModelica . . . . .	353
Parallel Model Execution on Many Cores . . . . .	363
A toolchain for Rapid Control Prototyping using Rexroth controllers and open source software . . . . .	371
Modular Multi-Rate and Multi-Method Real-Time Simulation . . . . .	381
<b>Session 3A: Automotive Applications: FMI &amp; HIL</b>	<b>395</b>
Significant Reduction of Validation Efforts for Dynamic Light Functions with FMI for Multi-Domain Integration and Test Platform . . . . .	395
Hardware In The Loop Simulation with Modelica - A Design Tool for Thermal Management Systems .	401
Integrated Vehicle Thermal Management in Modelica: Overview and Applications . . . . .	409
Virtual Integration for hybrid powertrain development, using FMI and Modelica models . . . . .	419
<b>Session 3B: Fault Handling and Safety Issues in Modelica</b>	<b>427</b>
General fault triggering architecture to trigger model faults in Modelica using a standardized blockset	427
Using Fault Augmented Modelica Models for Diagnostics . . . . .	437
From Modelica Models to Fault Diagnosis in Air Handling Units . . . . .	447
Simulation for verification and validation of functional safety . . . . .	455
<b>Session 3C: Novel Modelica Applications and Libraries</b>	<b>465</b>
The Foundation of the DLR RailwayDynamics Library: the Wheel-Rail-Contact . . . . .	465
Human-Nature Interaction in World Modeling with Modelica . . . . .	477
1D/2D Cellular Automata Modeling with Modelica . . . . .	489
Physiolibrary - Modelica library for Physiology . . . . .	499
<b>Session 3D: Electrical Power Systems</b>	<b>507</b>
Modelling of Electrical Power Systems with Dynamic Phasors in Modelica . . . . .	507
Flexible modeling of electrical power systems - the Modelica PowerSystems library . . . . .	515
Implementation of a Multi-Level Power Electronic Inverter Library in Modelica . . . . .	523
Mixed phasor and time domain modelling of AC networks with changeover management . . . . .	533
<b>Session 3E: Modelica Tools 2</b>	<b>543</b>
impact - A Modelica Package Manager . . . . .	543
MoUnit - A Framework for Automatic Modelica Model Testing . . . . .	549
Modeling Parameter Sensitivities via Equation-based Algorithmic Differentiation Techniques: The ADMSL.Electrical.Analog Library . . . . .	557
Modelica Based Parser Generator with Good Error Handling . . . . .	567
<b>Session 4A: Aerospace Applications 1</b>	<b>577</b>
Nonlinear inverse models for the control of satellites with flexible structures . . . . .	577
Modelica Stage Separation Dynamics Modeling for End-to-End Launch Vehicle Trajectory Simulations	589
A Modelica Library for Scalable Modelling of Aircraft Environmental Control Systems . . . . .	599
<b>Session 4B: Industrial Equipment</b>	<b>609</b>
Model-Based Energy Recuperation of Multi-Axis Machines . . . . .	609
A Generalized Power-Based Modelica Library with Application to an Industrial Hydraulic Plant . . .	617
Physical Design of Hydraulic Valves in Modelica . . . . .	627

<b>Session 4C: Control Applications</b>	<b>637</b>
Exploiting Actuator Limits with Feedforward Control based on Inverse Models . . . . .	637
An FMI-based Framework for State and Parameter Estimation . . . . .	647
Grey-box Building Models for Model Order Reduction and Control . . . . .	657
<b>Session 4D: Thermofluid Systems, Models and Libraries 1</b>	<b>667</b>
Interfacing Models for Thermal Separation Processes with Fluid Property Data from External Sources	667
Development of a Real-Time Fuel Processor Model for HIL Simulation . . . . .	675
ThermoCycle: A Modelica library for the simulation of thermodynamic systems . . . . .	683
<b>Session 4E: Hybrid Systems</b>	<b>693</b>
An Operational Semantics for Hybrid Systems Involving Behavioral Abstraction . . . . .	693
An example of beneficial use of variable-structure modeling to enhance an existing rocket model . . .	707
Efficient Monte Carlo simulation of stochastic hybrid systems . . . . .	715
<b>Session 5A: Aerospace Applications 2</b>	<b>727</b>
The Modelica BehaviorTrees Library: Mission Planning in Continuous-Time for Unmanned Aircraft .	727
Multi-Level Library of Electrical Machines for Aerospace Applications . . . . .	737
Modelica for large scale aircraft electrical network V&V . . . . .	747
Implementation of a Modelica Library for Simulation of Electromechanical Actuators for Aircraft and Helicopters . . . . .	757
<b>Session 5B: Power, Energy &amp; Process Applications 1</b>	<b>767</b>
An Optimization Framework for Dynamic Hybrid Energy Systems . . . . .	767
Industrial application of optimization with Modelica and Optimica using intelligent Python scripting .	777
Simulation of Smart-Grid Models using Quantization-Based Integration Methods . . . . .	787
On the Simulation of Offshore Oil Facilities at the System Level. . . . .	799
<b>Session 5C: Numerical Aspects of Modelica Tools</b>	<b>809</b>
Parameter Selection in a Combined Cycle Power Plant . . . . .	809
Restarting algorithms for simulation problems with discontinuities . . . . .	819
Discontinuities handled with events in Assimulo . . . . .	827
Noise Generation for Continuous System Simulation . . . . .	837
<b>Session 5D: Thermofluid Systems, Models and Libraries 2</b>	<b>847</b>
A physical solution for solving the zero-flow singularity in static thermal-hydraulics mixing models . .	847
Advanced Hybrid Model for Borefield Heat Exchanger Performance Evaluation, an Implementation in Modelica . . . . .	857
Superheat Control with a Dynamic Inverse Model . . . . .	867
Adsorption energy systems library - Modeling adsorption based chillers, heat pumps, thermal storages and desiccant systems . . . . .	875
<b>Session 5E: Modelica Tools 3</b>	<b>885</b>
A new Implementation of the N-D Lookup Tables . . . . .	885
Remarks on the Implementation of the Modelica Standard Tables . . . . .	893
The DLR Visualization Library - Recent development and applications . . . . .	899
Automated Modelica Package Generation of Parameterized Multibody Systems in CATIA . . . . .	913
<b>Session 6A: Mechanical Systems</b>	<b>923</b>
Modelling elastomer buffers with DyMoRail . . . . .	923
A Modelica Contact Library for Idealized Simulation of Independently Defined Contact Surfaces . . .	929
The OneWind Modelica Library for Wind Turbine Simulation with Flexible Structure - Modal Reduction Method in Modelica . . . . .	939
Simulating Collisions within the Modelica MultiBody library . . . . .	949
<b>Session 6B: Power, Energy &amp; Process Applications 2</b>	<b>959</b>
Short-term production planning for district heating networks with JModelica.org . . . . .	959
Modelling the system dynamics of islanding asynchronous generators . . . . .	969
Hybrid Energy System Modeling in Modelica . . . . .	979
Dynamic Modeling of Small Modular Nuclear Reactors using MoDSim . . . . .	989

<b>Session 6C: Optimization Applications and Methods</b>	<b>999</b>
Modified Multiple Shooting Combined with Collocation Method in JModelica.org with Symbolic Calculations . . . . .	999
DOML - a Compiler Environment for Dynamic Optimization Supporting Multiple Solvers . . . . .	1007
Efficient Implementation of Collocation Methods for Optimization using OpenModelica and ADOL-C . . . . .	1017
Symbolic Transformations of Dynamic Optimization Problems . . . . .	1027
<b>Session 6D: Thermal Power Processes</b>	<b>1037</b>
Modelling a Lignite Power Plant in Modelica to Evaluate the Effects of Dynamic Operation and Offering Grid Services . . . . .	1037
Use of External Fluid Property Code in Modelica for Modelling of a Pre-combustion CO <sub>2</sub> Capture Process Involving Multi-Component, Two-Phase Fluids . . . . .	1047
Dynamic modelling of a parabolic trough solar power plant . . . . .	1057
Testing Power Plant Control Systems in Modelica . . . . .	1067
<b>Session 6E: Web-related Modelica Tools</b>	<b>1073</b>
Vehicle Thermal Management – A Case Study in Web-Based Engineering Analysis . . . . .	1073
recon – Web and network friendly simulation data formats . . . . .	1081
IDOS - (also) a Web Based Tool for Calibrating Modelica Models . . . . .	1095
Client-side Modelica powered by Python or JavaScript . . . . .	1105
<b>Poster Session</b>	<b>1113</b>
Dynamic modelling of a Condenser with the ThermoSysPro Library . . . . .	1113
Wavelet Library for Modelica . . . . .	1123
Model-based Verification and Optimization of Batteries for Mobile Power Applications . . . . .	1131
Systems Physics Library . . . . .	1137
Implementation of the Omni Vehicle Dynamics on Modelica . . . . .	1143
Control and Characteristic Map Generation of Permanent Magnet Synchronous Machines and Induction Machines with Squirrel Cage . . . . .	1151
BuildSysPro: a Modelica library for modelling buildings and energy systems . . . . .	1161
Efficient Numerical Integration of Dynamical Systems based on Structural-Algebraic Regularization avoiding State Selection . . . . .	1171
Symbolic Initialization of Over-determined Higher-index Models . . . . .	1179
Proposal for standardization of Heat Transfer Modelling in NewThermal Library . . . . .	1189
A Modelica Power System Component Library for Model Validation and Parameter Identification . . . . .	1195
Modelica Model for the youBot Manipulator . . . . .	1205
Equation based parallelization of Modelica models . . . . .	1213
Simulation of 2-dimensional flows in Modelica with the Cascaded Digital Lattice Boltzmann Method . . . . .	1221
FORM-L: A MODELICA Extension for Properties Modelling Illustrated on a Practical Example . . . . .	1227
Statecharts as a Means to Control Plant Models in LMS Imagine.Lab AMESim . . . . .	1237
Integration of OpenModelica in Ptolemy II . . . . .	1247
Extending JGrafchart with Support for FMI for Co-Simulation . . . . .	1257
Development of Custom Workflows for Simulation and Analysis of Functional Mock-up Units . . . . .	1265
A Medium Model for the Refrigerant Propane for Fast and Accurate Dynamic Simulations . . . . .	1271
Consistent Simulation Environment with FMI based Tool Chain . . . . .	1277
A MATLAB to Modelica Translator . . . . .	1285
Setting up a framework for model predictive control with moving horizon state estimation using JModelica . . . . .	1295
<b>Exhibitors</b>	<b>1305</b>
BAUSCH-GALL . . . . .	1305
CENIT AG . . . . .	1305
Claytex . . . . .	1305
Concurrent Real-Time . . . . .	1305
CyDesign Labs . . . . .	1306
D2T . . . . .	1306

# Modelica Evolution – From My Perspective

Hilding Elmqvist  
Dassault Systèmes  
Ideon Science Park, SE-223 70 Lund, Sweden  
Hilding.Elmqvist@3DS.com

## Abstract

This paper intends to tell the story of Modelica ([www.Modelica.org](http://www.Modelica.org)) from the author's perspective. It is a fantastic saga that for me started in April 1976. The saga includes studying the needs, the original idea, the development of a solution, waiting for mature hardware technology, a start-up company, a fantastic collaboration, an automotive company caring for its software supplier, how to get momentum by standards collaboration, forming the right team, and the magic phone call from the right company.

*Keywords:* Simnon; Dymola; Modelica; Physical Modeling; DAE; Modelica Association

## 1 Introduction

In order to describe Modelica evolution it is important to start by describing Dymola, Dynamic Modeling Language, since many of the original features of Modelica are taken from Dymola.

The paper then describes forming the company Dynasim and the important initial research collaborations. The initial Modelica design work and the Modelica community are then discussed. The paper ends with a discussion about Modelica future. Most of the material is presented in chronological order.

For an overview of other simulation tools, see (Åström, et.al., 1998).

I propose that other key contributors to Modelica evolution, Martin Otter, Peter Fritzson and many others, write similar papers from their perspectives in particular since this paper has a focus on the work before Modelica and gives my perspective.

## 2 Dynamic Modeling Language

When looking for a master thesis project in autumn 1971, the Automatic Control Department, Lund Institute of Technology wanted to develop a simulation program where the user could input the models using

mathematical expressions. I was just studying compiler technology, so I considered this project perfect for me. The result was Simnon (SIMulation of NON-linear systems): (Elmqvist, 1975, 1977a). A novel feature was that a mixture of continuous time and discrete time systems could be simulated, i.e. perfect for simulation of sampled data control systems which were becoming very important at that time.

However, I was not satisfied with the approach as a basis for my PhD thesis, since it was based on submodels with inputs and outputs. I therefore wanted to investigate the fundamentals of modeling which my professor Karl Johan Åström supported. In April 1976, I was studying a report with about 200 pages about a drum-boiler model written by Sture Lindahl (Lindahl, 1976). The report was very systematic, showing how the equations were organized for the drum, the super heaters, the turbines, etc., i.e. the approach was object oriented. The modeling started by stating the relationships as general equations. Then the derivations were shown how to put them into state space form in order to be able to simulate using Simnon. These derivations involved manual symbolic manipulation of individual equations to solve for the unknown, solving linear systems of equations (see excerpt from report below), unrolling Newton's algorithm a fix number of times to solve nonlinear systems of equations, and differentiating certain equations when there were constraints between differentiated variables (nowadays called index reduction).

model

water - risers

large drum

large risers

$$\frac{d}{dt} [c_{dm8} m_{dm8} T_{dm8} + (V_{dl8} - V_{ds8}) \rho_{dw8} h_{dw8} + (V_{ds2} + V_{ds8}) \rho_{ds2} h_{ds2}] =$$
$$= q_{dm8} + w_{dl5} h_{dl4} - w_{ps1} h_{ds2} - w_{dw8} h_{dw8} \quad (9.1)$$

The mass balance the steam-water mixture in the risers and the steam in the drum becomes:

$$\frac{d}{dt} [(V_{dl8} - V_{ds8}) \rho_{dw8} + (V_{ds2} + V_{ds8}) \rho_{ds2}] =$$
$$= w_{dl5} - w_{ps1} - w_{dw8} \quad (9.2)$$

Multiplication of equation (9.2) by  $h_{dw8}$  and subtraction from equation (9.1) gives:

Just before Easter 1976, I realized what I needed to do: design a new language allowing general equations, having a class concept for object oriented modeling (I was used to Simula so that was natural) and having a structured feature to describe interaction between submodels (called cut). The language was called Dymola for DYnamic MODELing LAnguage (Elmqvist, 1977a, 1978, 1979a, 1979b).

An example in the Dymola language of an electrical component is shown below. It describes a pin A characterized by an across variable  $V_a$  and a through variable  $I$ . Pin B has correspondingly  $V_b$ . The through variable of B is also  $I$  but with a preceding minus sign showing that the currents of pins A and B sum to zero. In Dymola, all variables were of real type. The der operator is the same as in Modelica. The path concept was introduced in order to allow operators for series-, parallel- and loop-connections. Such a concept is not used in Modelica since connections are typically drawn graphically.

```

model type capacitor
  cut A (Va / I) B (Vb / -I)
  main cut C [A B]
  main path P <A - B>
  local V
  parameter C
  V = Va - Vb
  C*der(V) = I
end

```

Consider the following electrical circuit:

Using a library of “model types”: resistor, capacitor, voltage and Common, the circuit could be described as follows;

```

model Network
  submodel(resistor) R1 R2 R3
  submodel(capacitor) C
  submodel(voltage) E
  submodel Common
  input u
  output y
  connect Common to E to R1 to (C par (R2 to R3)) to Common
  E.V = u
  y = R3.Va
end

```

The “to” operator means series connection and “par” means parallel connection.

The trouble was then to figure out how to simulate such a model. I had used the symbolic package REDUCE and started to write symbolic manipulations in LISP. But how to know what variable to

solve for in each equation? The naïve approach is: look for equations with only one unknown, mark those as known and repeat. The problem is that there can be mutual dependencies, i.e. algebraic loops for which this approach does not work. And mutual dependencies were normal in the way Lindahl did his modeling, so the language could not be restricted to avoid algebraic loops. I invented my own algorithms using binary incidence matrices. However, these were  $O(n^3)$ , so they would not scale.

At that time one had to go to the university library to get help in doing a computerized literature search (no Alta Vista or Google being available). I found that graph theoretical algorithms were  $O(n)$ . The graphs are bipartite, i.e. consists of two types of nodes corresponding to equations and variables. An edge between a variable and an equation means that the variable appears in that equation. A report from the University of Umeå analyzed several algorithms for Assignment or matching which corresponded to finding out what variable to solve for in each equation. Furthermore, Tarjans algorithm would find strongly connected components in a directed graph corresponding to minimal systems of simultaneous equations and sort them into a sequence suitable for solving one system at a time, i.e. the incidence matrix becomes block lower triangular (BLT).

Lindahl sometimes differentiated equations when potential states were constrained. The Jacobian is then always singular. I designed an algorithm to find what equations to differentiate and tested it successfully on some small examples. Fortunately, Costas Pantelides and Sven Erik Mattsson later figured out suitable algorithms, (Pantelides (1988), (Mattsson, Söderlind, 1993).

To test the language ideas and the algorithms, I wrote a program in the object oriented programming language Simula, which is included in my thesis, (Elmqvist, 1978). I tested it successfully on a few examples from different domains: electronics, mechanical, thermodynamics, and electrical power distribution. As an example, the program found one system of equations for solving accelerations and forces of mechanical systems corresponding to the need to invert the mass matrix. The drum boiler model could now be formulated in 15 pages using original equations defined only once for each class and no need for manual symbolic manipulation of the equations. The total model had about 250 non-trivial equations and 11 systems of simultaneous equations.

But there was one big problem: lack of computer memory for symbolic manipulation. I was barely able to translate the drum boiler model on a Univac 1108 computer having only 64 kWords of 36 bits of

memory accessible for the user and the garbage collector had to work hard. So the hardware technology at that time was not mature enough for realistic industrial problems.

After my thesis in May 1978 (Elmqvist, 1978), I spent one year as a post doc at Computer Science Department at Stanford University. I took all the courses in languages and compilers given by John Hennessy (who later became President of Stanford University). Working in a compiler project regarding parametric types, (Hennessy, Elmqvist, 1982) was a very useful experience.

I then returned to the Automatic Control department for a project on Languages for Implementation of Control Systems (LICS), (Elmqvist, 1985). In addition to language elements, we also considered the relations to graphics and were able to acquire a mouse. That gave valuable knowhow which later became meta comments in Dymola and adopted in Modelica as graphical annotations. In order to achieve sufficient speed for navigating in hierarchical structures, we developed special raster graphics hardware and a font generation program. The LICS program was developed on a VAX-11 computer and ported to an Apollo DN 600 workstation and demonstrated at the second IEEE Computer Aided Control Systems Design Symposium in 1983 at MIT with high interest since it showed several novel interaction principles such as “information zooming”.

During this project, we also translated the Dymola program from Simula to Pascal since there was no Simula compiler on the VAX. This enabled handling larger models due to the linear address space of the VAX. Francois Cellier got a copy of the Pascal version. The importance will be clear later.

The LICS project got an industrial follow-up since I worked for the company SattControl 1984-1992. We developed a distributed control system called SattLine (Elmqvist, 1991a, 1991b, 1992). This experience later influenced the design of hybrid features of Modelica.

### 3 The Company Dynasim

In August 1991, an important thing happened. I was working in Toronto for two years and attended a seminar at the university by a colleague of Francois Cellier. Francois had moved to Tucson, Arizona and we had lost contact. During our renewed contacts I learnt that Francois was writing a book: Continuous Systems Modeling (Cellier, 1991). I got the manuscript and was overwhelmed! It described Dymola and used Dymola for modeling of many examples.

I also met Peter Fritzson in the summer 1991 at a computer language conference in Toronto and became aware of his work on designing a modeling language, ObjectMath, which combined features of Computer Algebra languages and Object Oriented Programming. I successfully converted some ObjectMath models to Dymola.

These were two of the tipping points that made me resume the work on Dymola since I understood that there was finally an interest in equation based modeling. The third tipping point was the release of Windows 3.0 since the memory barrier of 640 kBytes linear memory was removed.

Cellier and I started to work together and we wrote a paper for a CACE conference in Napa, California (Cellier, Elmqvist, 1992) which later became an article in IEEE Control Systems (Cellier, Elmqvist, 1993). I continued to make development on the Pascal version of Dymola for some time and used the p2c (Pascal to C) translator to facilitate using a C compiler. Sven Erik Mattsson had given me a copy of the article by Costas Pantelides about index reduction, (Pantelides, 1988). I incorporated this in Dymola for the paper.

At the same conference, Sven Erik presented the dummy derivative method including automatic state selection after index reduction based on Pantelides algorithm (Mattsson, 1992).

In Napa, I met Georg Grübel, DLR (Deutsches Zentrum für Luft- und Raumfahrt) and learnt that Cellier would spend the summer 1992 at DLR in Oberpfaffenhofen, Germany. It was decided that Cellier would introduce the Dymola technology at DLR. Martin Otter immediately got hooked and started to implement a library of MultiBody components which was later published in (Otter, et.al., 1996). Francois remembers: “Four weeks into my visit, Martin came to my office on Monday morning, telling me that he now could throw away his program “myRobot” that he had previously developed for the simulation of tree-structured robots. Over the weekend, he had re-implemented his robot model in Dymola, which turned out to be much more elegant and flexible.”

I moved back to Sweden and started the company Dynasim in August 1992. DLR realized the potential of the Dymola technology but also the needs to extend the Dymola language and the tool. For example, Dymola did not have **matrix support** then which is essential for MultiBody modeling. Fortunately, DLR could support further development financially which gave Dynasim important initial funding. Martin Otter and I have worked in close collaboration since then. We met for the first time at DLR Oberpfaffenhofen in August 1993 after one year of collaboration via e-mail.

We made a design for **modeling hybrid systems** in order to be able to model power electronics and phenomena such as friction, (Cellier, et.al., 1993) and (Otter, 1994). The concepts of instantaneous equations and event iterations were then introduced.

In July 1993, Dag Brück was employed especially to develop a **graphical user interface** enabling creating components and connecting them by drag and drop. Dag had worked in the Omola project at the Automatic Control Department, Lund.

A missing piece of the technology was to handle that the blocks corresponding to systems of simultaneous equations often got large but sparse. Tearing is a static technique to handle this problem. Our first attempt was to help the translator by introducing hints in the form of a residue operator, (Elmqvist, Otter, 1994). Shortly afterwards, Martin Otter and myself figured out an algorithm to automatically perform tearing, and the algorithm was introduced in Dymola. Dymola would then, for example, for a tree structured multibody model find a large linear system of equations involving accelerations, forces and torques and discover that it could be reduced to inverting a linear matrix of size equal to the number of degrees of freedom.

The efficiency of the code could be enhanced if structural and symbolic processing is made not only on the model equations but also on the discretization equations of the numerical integrator. We called it **inline integration**, (Elmqvist, et.al., 1995). This became very important for hardware-in-the-loop simulation. For example, this technique allows efficient use of implicit methods for multibody models since it combines inverting the mass matrix and solving the non-linear systems of equations.

The **early adopters** of this equation and object based modeling technology can be seen from the Dymola license numbers:

- 101: Francois Cellier, University of Arizona
- 102: Martin Otter, DLR
- 103: Rafael Huber, Dept. Ing. Sistemas, ESAIL, Barcelona, Spain
- 104: Sebastian Dormido, Depto. De Informatica y Automatica, UNED, Spanien
- 105: Michael Grimsberg, Lund Institute of Technology
- 106: Dieter Kraft, Dept of Mechanical Engineering, University of München
- 107: Jochen Seibold, Rechenzentrum University of Stuttgart

Ingrid Bausch-Gall early understood the potential of Dymola and Bausch-Gall GmbH became **distributor** in German speaking countries in September

1995. This was very important for growing the interest in the technology in Germany.

Bengt Jacobson, Machine and Vehicle Design, Chalmers Technical University was among the early adopters and started to use Dymola for powertrain development in a collaborative project with Volvo and Saab in 1995.

Jan Tuszynski at Sydkraft Konsult in Malmö, Sweden deployed Dymola for thermal power systems in 1995.

Sebastian Dormido organized a workshop in Avila, Spain summer 1996. Francois Cellier and I presented the principles of object-oriented equation based modeling.

Akira Ohata and Yutaka Hirano, Toyota Motor Corporation heard about Dymola during a presentation in Japan by Georg Grübel, DLR. They got Dymola licenses in middle of 1996 and started to use it for the **Toyota Prius development**. The multi-engineering modeling capability was necessary for the hybrid car development. However, they realized that the maturity of the Dymola software was not sufficient for large scale deployment and provided funding during 2 years starting end of 1997 regarding general GUI enhancements, GUI for Modelica, symbolic solver capabilities, etc. This was an essential funding allowing for expansion of Dynasim. In the end of 1998, Toyota Techno Service Corporation became distributor of Dymola in Japan with Takashi Matsuba and Rui Gao as technical support. In 2007, Rui Gao came to work for Dassault Systèmes.

Martin Otter visited Dynasim for two months in September and October 1996 and gave a lecture series on object oriented modeling of mechanical systems at the Automatic Control department at Lund Institute of Technology. We worked in particular on real-time simulation of hybrid systems such as automatic gearboxes. Martin was the main author of the **Dymola standard library** containing Blocks, Electrical, Rotational, and MultiBody components.

Hans-Jürg Wiessmann and Bernhard Bachmann, ABB, Baden-Dättwil in Switzerland became users of Dymola in 1996 for **power electronics** modeling and HILS (Hardware-In-the-Loop Simulation). Bernhard spent 4 weeks at Dynasim in March 1998. He then proposed a simple state selection algorithm which was used in Dymola before the dummy derivative algorithm of Sven Erik Mattsson was included.

Peter Beater, then at University of Paderborn, started to develop a **Hydraulics library** beginning of 1997. This was later converted to Modelica and sold to Modelon in 2006.

Rüdiger Franke (then at University of Ilmenau) started to use Dymola with partial Modelica support in 1997 for optimization of thermodynamic systems.

I started to completely rewrite the **symbolic engine** of Dymola in July 1997. Until then the old version converted to C from my thesis had been used. I used C++ Standard Template Library successfully on several hundred thousands of equations and Dag Brück implemented counted pointers to handle allocation and de-allocation of memory automatically.

Martin Otter held his first modeling course based on Dymola at Technical University of Munich for students of electrical and mechanical engineering in the year 1997.

Mike Dempsey (then at Rover) started to evaluate Dymola in 1998 for powertrain modeling.

Sven Erik Mattsson was employed in August 1998. He had a perfect background from the Omola project (Andersson, 1994) since he implemented the symbolic engine of OmSim.

Hans Olsson was employed in January 1999 and had a complementing background regarding numeric and GODESS solvers. So now, the **dream team** was formed with Dag, Sven Erik, Hans and me together with collaboration with Martin Otter.

Sven Erik, Dag, Hilding, Hans

Roger Larsson was utilized as a consultant from June 2004 to accelerate building the business side of Dynasim.

## 4 Modelica Language Design

In spring 1996, I had lunch with Prof Karl Johan Åström and Sven Erik Mattsson from the Automatic Control department, Lund University. Sven Erik was the project leader of the Omola project (Andersson, 1994). We discussed the need for unification of our efforts on Omola and Dymola.

In May 1996, I attended a workshop in Brussels regarding simulation methodologies organized by Hans Vangheluwe. I then, for the first time, met Per Sahlin, Bris Data AB, Stockholm (later renamed to Equa AB) and Alexandre Jeandel, Gas de France, Paris who both were working on equation oriented modeling languages: NMF and Allan respectively.

I then realized that it was time for a **global unified language design initiative**. Modeling requires reuse of stored knowledge, i.e. there must be a standard language. It does not make sense that various tool vendors invent their own language and that a new language is created for every Ph.D. thesis on modeling.

So, I initially phoned Sven Erik Mattsson, Martin Otter, Per Sahlin and Alexander Jeandel to discuss starting a collaborative language design effort. We agreed to meet in Lund on September 2-4, 1996. The participants are seen below, from left to right: Martin Otter, Alexandre Jeandel, Per Sahlin, Sven Erik Mattsson, Bernt Nilsson and me. Dag Brück participated partially and took the photo.

The picture below shows participants of the 75<sup>th</sup> Modelica design meeting in Lund May 2012.

You might wonder about the name Modelica. The name was invented during one of the lunches of the first meeting. I don't recall who said it first. We quickly checked the usage in Alta Vista. It is used in Spanish for a role model.

Sven Erik Mattsson organized a COSY workshop in Lund the week after with about 20 participants.

Our language design ideas were then presented, i.e. it got some immediate attention. We met Costas Pantelides at this workshop and convinced him to arrange the 3<sup>rd</sup> design meeting in London. One of the goals was to get in closer contact and cooperate together. Unfortunately, Costas decided later to not join the Modelica development and continued with his own modeling language, gPROMS.

The language design effort initially got a small travel funding from the ESPRIT project "Simulation in Europe Basic Research Working Group (SiE-WG)". It was later organized as the EuroSim Modelica Technical Committee 1 and the Technical Chapter on Modelica within Society for Computer Simulation. I was the chairman for 3 years and then handed over to Martin Otter, the present chairman.

In the year 2000, the non-profit Modelica Association was formed in Linköping, Sweden to formalize the continually evolving Modelica language and the development of the free Modelica Standard Library.

**Modelica 1.0** was released after one year design in September 1997. It had classes, inheritance, class parameters (replaceable classes and components) equations, blocks, connectors, functions, etc. I remember an intense debate at the release meeting when Peter Fritzson, who joined the Modelica effort early 1997, argued for including functions and I argued to wait until the next release. Thank you Peter for pushing. Hybrid modeling features were included in version 1.1 released in December 1998.

Dag Brück started to implement a Modelica compiler immediately after the first design meeting. It initially output Dymola code in order that the Modelica models could be simulated. Dymola has been used as a platform for the design group to test all features during Modelica evolution. The first version of **Dymola which officially supported Modelica** was version 4.0 released July 1, 1999. We worked all night until 6.10 A.M in the morning since we wanted it to be released first half of 1999 (in at least some part of the world). The meaning of Dymola then had to be changed to DYNAMIC MODELing LABORatory. It also had a conversion option to convert Dymola models and packages to Modelica. Martin Otter was the main author of the **Modelica Standard Library (MSL)**. Later, many people contributed to the development of MSL and the current version of MSL has Modelica models from about 30 people.

Michael Tiller, then at Ford, became aware of Dymola (the language) but got really interested in Modelica due to the open specification. He became the first Dymola/Modelica power user in beginning of 1999 and helped us test our Modelica translator. He also wrote the first book about Modelica: Introduction to Physical Modeling with Modelica, (Tiller,

2001). We provided a demo version of Dymola which was shipped with the book. Ford was also interested in converting Adams models, so we made a translator from adm-files to Modelica MultiBody. Andreas Möller (now my son-in-law) developed a supporting Modelica library. To handle these large models, we had to enhance the internal data structures of Dymola. In May 2000, we could simulate an entire vehicle, (Bowles, et.al., 2001).

Sven Erik Mattsson invited Hubertus Tummescheit in 1998 to make a Ph.D. thesis at the Automatic Control department, Lund. Hubertus and Jonas Eborn developed a comprehensive Modelica library for thermo-dynamical systems which broadened the applicability of Modelica. Hubertus organized the first Modelica Workshop in Lund in 2000 with 80 participants. Gerhard Schmitz and his group in Hamburg utilized this library for building a library for air-conditioning modeling. DaimlerChrysler, BMW, Volkswagen and Audi wanted to standardize on a modeling format to allow them to exchange models with their suppliers. During the autumn 2003 there was intense work including benchmarking various tools. However, we needed to form an organization that could supply and support these customers. Hubertus and Jonas then worked at UTRC, USA. I called Hubertus in December 2003 and asked him to come back to Lund and help organizing the effort. He was back before Christmas. This led to founding of Modelon AB by Hubertus Tummescheit, Jonas Eborn, Magnus Gäfvert, Johan Andreasson and me in 2004.

Peter Fritzson made a formal specification of Modelica in 1998 which later led to the open source implementation OpenModelica, (Fritzson, 2002).

Hans Olsson took the responsibility in 2000 of being the editor of the Modelica specification, i.e. to organize the process of resolving all change requests.

Peter Fritzson wrote the book **Principles of Object Oriented Modeling and Simulation with Modelica 2.1** which was published in 2003, (Fritzson, 2003).

## 5 Dassault Systèmes

Francois Bichet, Dassault Systèmes called in November 2005 and asked if he and Dominique Florack, VP of R&D could visit Dynasim. I made a presentation of the company and the technology and got invited to Paris for presentations to a larger group at Dassault Systèmes and for further discussions. I then got the question if Dynasim was for sale. I considered such a deal as a perfect marriage since I believe systems engineering, modeling and

simulation must be married to 3D and CAD. An intense period of meetings and discussions led to a letter of intent signed before Christmas 2005. The deal was closed on April 2, 2006 and announced at the Dassault Systèmes DevCon Conference in June, 2006.

The first years of joining such a big company were somewhat turbulent for us. Dymola and Modelica represented a new world for some of the managers at Dassault Systèmes HQ and the Dynasim team was too remote from HQ. The situation was corrected in the beginning of 2010 with new manager for CATIA Systems, I was appointed as Chief Technology Officer for Systems reporting to Philippe Laufer, now CEO of CATIA. Dan Henriksson became manager of the Dassault Systèmes Lund team and Martin Malmheden relocated to Dassault Systèmes in Paris to help in the technology transfer. This enabled me to focus on technical aspects and in particular, together with Sven Erik Mattsson, to work on new features such as the synchronous extensions to Modelica and multi core simulation.

## 6 Modelica Community

The Modelica community is now growing rapidly. There are 9 tools having at least partial support for the Modelica language, see [www.Modelica.org/tools](http://www.Modelica.org/tools). There are more than 1300 models in the Modelica Standard Library. A Modelica compliance test suit with more than 1000 tricky models is available for checking tool compliance. It is planned that a web page with compliance status will be available.

We are now organizing the 10<sup>th</sup> Modelica Conference. More than 22 Ph.D. theses, 800 papers and articles have been published related to Modelica.

Several large EU projects have been activated: RealSim, EuroSysLib, Modelisar, OpenProd, and Modrio with more than 100 man-years of effort.

The Modelica Association is also growing, now having more than 100 individual members and more than 10 industrial members. People from the synchronous language community have joined after Philippe Laufer suggested I should attend a meeting with them in Paris in October 2010. The synchronous Modelica features were developed with the help of Albert Benveniste, Marc Pouzet, Francois Dupont and others, (Elmqvist, et.al., 2012).

The scope of Modelica Association is also growing to also incorporate the FMI development.

## 7 Modelica Future

This section discusses a few possible directions for the future of Modelica. In most cases it is a matter of both tool support and various extensions to Modelica.

As mentioned before, systems engineering also need to take **3D aspects** into account, such as mass and inertia calculated from actual shape and materials, collision handling, etc. It is also important to have consistent parameterization of the behavior model and the shapes. It should be possible to initially use a simplified model for concept studies and gradually replace submodels when CAD parts or a kinematic model become available as illustrated below:

Modelica gives the possibility to compose more and more detailed models since model components can be reused. This means that simulation needs to be faster. One possibility is then to use multi-core technology. Recent advances with more than 1000 cores (www.Kalray.com) show the potential. The problem is then how to utilize this enormous processing power in a user friendly way. Partitioning needs to be made automatically. Modelica gives good possibility to automatically partition the model equation execution into separate threads since it is a declarative language based on equations. Early developments are described in (Aronsson, et.al. 2002). A new paper (Elmqvist, Mattsson, 2014) describes a method to **automatically parallelize model equations** implemented in Dymola. A speed-up of 3.4 times has been achieved using 4 cores/8 threads.

Modelica models and simulations is one part of systems engineering. It is important to **enable various tool chains** including sensitivity analysis, optimization, Monte Carlo simulations, linear analysis, code generation, etc. It should be possible to define a process flow that can be reused if some early requirements or designs need to be changed. It is important with standardized interfaces. A subgroup of Modelica Association is working on defining an XML format for various levels of Modelica representation, source, flattened, solved, etc. This will enable various backend tools such as fault tree analysis and code generation. Another subgroup is working on how to store meta information in a standard-

ized way, for example, for optimization (Zimmer, et.al., 2014).

A subtask within the MODRIO project is to enable **modeling of multi-mode and stochastic systems**, for example, to model failing components. A generalization of synchronous state machines to continuous time and that the number of states of a system can change at events is proposed, (Elmqvist, et.al., 2014).

Modelica now has quite limited data structures, i.e. only arrays and records are allowed. It is not possible to define recursive data structures or maps. Such **advanced data structures** are, for example, needed for advanced controllers, scripting, and meta information for work flows. MetaModelica has successfully incorporated such features already 2005 (Fritzson, 2005).

We in the Modelica Association also want to define more features of Modelica using a **Modelica Kernel language**. This would enable, for example, defining connection semantics, state machine semantics, etc. in the Modelica Kernel language. A prerequisite for this approach is that more advanced data structures are available in the Modelica Kernel language.

Most Modelica tools allow several views of a model or library such as Diagram, Icon, Modelica Text, Documentation, Package tree view. However, **SysML offers several additional useful views** such as inheritance tree, component hierarchy, etc. Such views can be automatically generated from Modelica. For example a Block Definition Diagram (bdd) of SysML for the CoupledClutches example might look as shown below using a Layered Digraph layout algorithm.

The question about **standardization** of Modelica as ANSI or IEEE standard is frequently raised. The members of Modelica Association want to wait because we feel there are some unifications and enhancements that need to be made first, such as simplification and extension of generics (redeclare) and Modelica Kernel language.

## 8 Conclusions

The Modelica effort is a truly multi-disciplinary challenge involving compiler technology, graph theory, computer algebra, numerical mathematics, etc. Furthermore, Modelica library development requires skills from many engineering domains such as electronics, mechanics, and thermo-dynamics. The beauty of Modelica is that it enables them all to express themselves in the same language.

An important driving force behind Modelica is to enable storing engineering knowledge in a form that can be reused. This enables more realistic simulations of the complex systems now being designed. It gives the engineers a more interesting work place since tedious manual model development is not needed. This also has the effect that many manual errors are avoided and the simulation results can be better trusted.

Another driving force has been and is the joy of being part of a community with the desire to change the design methodology to become model based. Many hard problems have had to be solved which means that there has been many exciting moments of success.

It seems fair to state that Modelica has already been proven as a means for storing engineering knowhow in a reusable form. The equation orientation means that equations from engineering books can often be reused directly. There is no need to manually transform the equations since the tools do that for you. It is a neutral form which already is supported by many tools. So a good stable platform has been established.

## 9 Acknowledgements

I am thankful to all persons mentioned in this paper and to many others that enabled this saga to take place.

In particular, I want to thank my thesis advisor and mentor Prof. Karl Johan Åström for guidance and for believing in me that this direction would be possible and useful. He wrote in a certificate about me: "He walks his own ways". It took several years until I understood how positive that was.

Thanks to Sture Lindahl for writing such a well-structured and comprehensive report about power systems modeling which could be formalized.

Francois Cellier was the first user to really understand the principles and power of Dymola, introducing Dymola in his courses in Tucson and in his book. Thank you, Francois.

I want to thank Georg Grübel for helping financing the early developments and for introducing Dymola in Japan.

Without the devoted work by Martin Otter, Modelica would not have succeeded. Thank you, Martin, for your dedication, hard work and fantastic collaboration during 22 years.

Yutaka Hirano and Akira Ohata understood the industrial significance of Dymola but also understood that in order to succeed, financial support was needed which I am very grateful for.

Francois Bichet followed the Modelica evolution for a long time before calling me. Thank you, Francois, for promoting Modelica and Dymola internally in Dassault Systèmes.

I want to thank my manager Philippe Laufer for believing in me and letting me use my own judgment for advancing the Modelica, Dymola and FMI technologies.

Dag Brück, Sven Erik Mattsson and Hans Olsson were absolutely essential for our success. Thank you for the creative, innovative and fun collaboration. I also want to thank all the other past and present members of the Dynasim/Dassault Systèmes Lund team for a great collaboration.

And most importantly, thanks to my wife Irène Lind Elmqvist who has supported and encouraged me for more than 40 years and for coping with the uncertainties of a start-up company. Thank you, Irène, for also taking me away from virtual reality to reality in places such as Namibia, South Africa, Tanzania, Botswana, Antarctica, Galapagos, New Zealand, Cook Islands; finding tigers in India and skiing in Åre.

## Abstract

The demand for model exchange between development partners will grow during the next years. The Functional Mockup Interface (FMI) is a well received tool independent approach for model exchange. The Original Equipment Manufacturers (OEM) have committed themselves to support FMI as exchange format for simulation models. Therefore, the FMI is a promising candidate to become the industry standard for model exchange and cross-company collaboration. In this paper, the FMI standard is evaluated from an industrial perspective.

*Keywords: FMI, industrial perspective, problem classification*

## 1 Introduction

There is a strong trend of virtualization in engineering, where simulation replaces real testing in order to develop faster, cheaper and with more system understanding. Therefore, system simulation is used in different phases of product development and gains importance within the entire product development cycle. The design of future products is done on the basis of simulation models.

### 1.1 Modeling and Simulation at Bosch

However, the simulation landscape in the field of system and component design in industry is very heterogeneous. At Bosch, there are more than 100 simulation tools with incompatible model representations in use, some of them are preferred tools for different physical or engineering domains. The picture becomes even more complex when looking at external partners such as Original Equipment Manufacturers (OEM) with a different set of preferred simulation tools. Today, there exist only proprietary ex-

change formats that are limited in functionality and only applicable to a limited number of tool combinations.

### 1.2 Approaches for modeling of complex systems and model exchange

There are two complementary approaches for modeling complex systems:

*White box modeling:* Modeling the entire system with one modeling language. This requires a modeling language that is suitable for different physical domains. This approach offers the possibility for deep system understanding by equation-based, object-oriented modeling and symbolic manipulation. MODELICA is an example for that approach.

*Black box model exchange:* Defining an interface for model exchange for standardized, tool-independent exchange format for simulation models is a complementary approach. It offers a way to cope with a heterogeneous simulation tool environment and allows using specialized tools for different physical domains. This approach offers also the possibility for know-how protection for model exchange in distributed collaborative system engineering. The Functional Mockup Interface (FMI) is a promising candidate to become the industry standard for this kind of model exchange and cross-company collaboration.

In the following, the black box model exchange with FMI is evaluated from an industrial perspective. Requirements on such an interface for industrial applications are

- *standardization* of the model interface (in order to be tool-independent),
- *availability* of a significant number of supporting tools,
- *easy-of-use* of the interface for simulation engineers,
- *adoption* of the standard in the specific industry domain,

- *accompanying documentation* and a reference process for the exchange of such black box models, and
- *maturity* of such an interface, i.e.,
  - no errors when importing FMUs from other sources and
  - reliable simulation results when using such an interface.

### 1.3 The Functional Mockup Interface for black box model exchange

The Functional Mockup Interface [1-4] has been developed to meet the requirements listed above. The requirement *standardization* and tool-independence is fulfilled by design. There is growing support for FMI by simulation tools (i.e., more than 40 listed on the FMI website), so the *availability* is given (although some often used simulation tools are still missing). The *easy-of-use* to some extent is also by design (e.g., XML-file for model information) and is realized quite well by the majority of exporting and importing simulation tools. The Global Automotive Advisory Group (GAAG) has committed itself to support FMI as exchange format for simulation models [5]. Thus, the broad *adoption* is at least planned. The *accompanying documentation* is addressed in the ProSTEP Smart Systems Engineering Project [6]. In the following the paper will focus on the *maturity* of the FMI standard or the maturity of the implementation respectively.

## 2 The Maturity of FMI

### 2.1 Maturity of FMI after the end of the MODELISAR project

As a result of the MODELISAR project, the FMI standard 1.0 was published and it was implemented by a growing number of modeling and simulation tools. In the MODELISAR project, requirements for FMI were derived from the beginning and tested for industrial applications. The performance of the FMI approach was demonstrated in 24 industrial applications [4]. Additional successful applications have been reported at the 8<sup>th</sup> and 9<sup>th</sup> Modelica Conference, see e.g. [7-10]. However, these examples were realized in some fixed combinations of FMU-exporting and importing tools.

In 2012, an internal benchmark at Bosch with three exporting tools (12 test FMUs exported) and five importing tools showed quite different results. The test examples range from a “model” containing a sine generator only, a bouncing ball, a spring-damper

system, an RC circuit to a thermal network. While some combinations worked quite well, other combinations did not work at all. Typical problems at that time were

- formal errors in the XML-file,
- errors during initialization,
- memory leakage, and
- different simulation results in different importing tools.

Test results for the bouncing ball example are as depicted in Figure 1. The model was created in tool 1. Then, it was exported as a Functional Mockup Unit (FMU) for model exchange. The import of the FMU in the same simulation tool was possible, but the simulation results were erroneous, see Figure 1. The simulation of the FMU was also not possible in four other simulation tools due to different errors, e.g.,

- failed assertions,
- two importing tools crashed during simulation, or
- unspecified error at import.

(a) Reference solution

(b) FMU simulation result in tool 1

Figure 1: Comparison of simulation results for a bouncing ball example (status March 2012)

At the same time, every tool could be listed on the FMI website in “green” and claim to support FMI as

depicted in Figure 2. The number of these tools increased very rapidly, but did not reflect the experience of the internal benchmark.

**FMI Support in Tools**  
Compatibility Table

The following modeling and simulation environments support or plan to support FMI 1.0 (alphabetical list):

Tools supporting FMI	Model-Exchange		Co-Simulation		Notes
	Export	Import	Slave	Master	
AMESim	Available	Available	Planned	Planned	Modelica environment from LMS-Imagine
ASIM	Planned	Planned	Planned	Planned	AUTOSAR Builder from Dassault Systèmes
Argeo Ace	Available	Available	Available	Available	Co-simulation environment with AUTOSAR and HL support
Building Controls Virtual Test Bed	Planned	Planned	Planned	Planned	Software environment, based on Ptolemy II, for co-simulation of, and data exchange with, building energy and control systems
CATIA V6R2013	Available	Available	Available	Available	Environment for Product Design and Innovation, including systems engineering tools based on Modelica, by Dassault Systèmes
ControlBuilder	Available	Available	Available	Available	Environment for IEC 61131-3 control applications from Dassault Systèmes
CosyMata	Available	Available	Available	Available	Co-simulation Environment from ChasTik
Cybernetica CENIT	Available	Available	Available	Planned	Industrial product for nonlinear Model Predictive Control (MPC) from Cybernetica
Cybernetica ModelFit	Available	Available	Available	Available	Software for model verification, state and parameter estimation, using logged process data, by Cybernetica
DSPplus	Planned	Planned	Planned	Planned	Fluid power simulation software from FLUIDON
Dynola 2013	Available	Available	Available	Available	Modelica environment from Dassault Systèmes
EnergyPlus	Available	Available	Available	Available	Whole building energy simulation program
FMI Library (from Modelon)	Available	Available	Available	Available	Open source (BSD) C library for integration of FMI technology in custom applications by Modelon
FMI add-on for NI VeriStand	Available	Available	Available	Available	Manages simulations with FMI for co-simulation V1.0, available from DQWave
FMU SDK	Available	Available	Available	Available	FMI Software Development Kit from QTronic
FMU Trust Centre	Available	Available	Available	Available	Cryptographic protection and signature of models including their safe PLM storage; secure authentication and authorization for protected (co-)simulation via Modeling and Co-Simulation environment by Modelon
IPG CarMaker JFMI	Planned	Planned	Planned	Planned	A Java Wrapper for the Functional Mock-up Interface, based on FMU SDK
JFMI	Available	Available	Available	Available	Open source Modelica environment from Modelon

## 2.2 A classification of possible problems in FMI-based simulation

The challenges encountered in the benchmark are classified and ordered with increasing maturity of the FMI standard:

- I. *Inconsistencies of the standard*
  - Source of problem: Standard
  - Examples: Ambiguities regarding naming conventions and structure of ZIP-file, XML model-description file
- II. *Formal errors in the FMU-File*
  - Source of problem: Exporting tool
  - Examples: Errors in XML and internal directory structure of ZIP-file
- III. *Formal interaction of importing tool with FMU*
  - Source of problem: Exporting or importing tool
  - Examples: Errors in calling functions; memory leakage

## IV. Simulation of one FMU (with solver of importing tool in case of model exchange)

- Source of problem: Exporting or importing tool
- Examples: Incorrect initialization; incorrect simulation result; incorrect event handling

## V. Simulation of multiple connected FMUs with solver for model exchange

- Source of problem: Solver or master algorithm of exporting/importing tool, overall system divided into several FMUs at unsuitable location
- Examples: Incorrect treatment of algebraic loops; numerical problems with FMUs with different time constants (stiffness)

These problem categories are summarized and ordered in Figure 3. The problem classes correspond to different stages in the simulation process. If an error occurs in one problem class, typically the simulation fails or the results are not reliable.

At the beginning of 2012, the FMI standard 1.0 was quite mature so that problem class I was not a big issue. But there occurred several problems corresponding to problem classes II to IV for exchanging even single FMUs between different tools and simulating them. Only the problem classes I to IV are FMI-specific; problem class V corresponds to typical simulation challenges of modular simulation with causal interfaces or co-simulation. Some of the problems in FMI-based simulation might be observed for the first time, because models have neither been exchanged nor been coupled in the past.

## 3 Implemented measures to improve maturity

The maturity issues of FMI-based simulation were addressed to the FMI community at the MODELICA/FMI meetings beginning early 2012. The discussions and input from other companies and users resulted in the call for quotation of an FMU

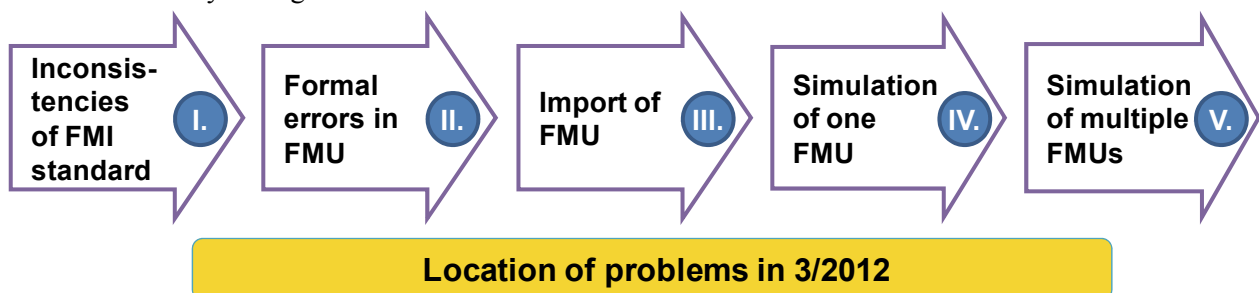

Figure 3: Classification of problems in FMI-based simulation

Compliance Checker and later of FMI Cross Checking rules. Bosch's application for membership in the FMI Steering Committee was accepted in January 2013. Since then Bosch is actively contributing at FMI design and steering committee meetings.

### 3.1 FMU Compliance Checker

The FMU Compliance Checker [11] is a software tool that was initiated by the MODELICA Association by a call in 04/2012 and was implemented by the company MODELON AB. It addresses problem classes II, III, and also partly IV (the tool contains only a very simple solver). In the first release only one FMU could be called and no inputs to the FMU could be provided. With a later release inputs to FMUs can be provided as CSV-files. The FMU Compliance Checker is a very valuable tool to check for formal errors of the FMU (see Figure 4).

Figure 4: Focus of FMU Compliance Checker and FMI Cross Checking

### 3.2 FMI Cross Checking

The FMI Cross Check Rules [12] were approved in February 2013 and focus on testing the quality of implementations of exporting and importing tools. It is defined how many FMUs an exporting tool must publish and for how many of these FMUs an importing tool must publish simulation results in order to get listed as “available” on the FMI-tools website [3]. As at the moment only single FMUs are tested, FMI Cross Checking at the moment focuses on problem class III and IV as depicted in Figure 4. As a side effect it will also show problems of class I and II.

Figure 5 shows a screenshot of the FMI Tools website [3] and an entry in green refers to an exporting or importing tool that has successfully passed FMI Cross Checking. An entry in orange shows that the corresponding FMI export or import is claimed to be available but is not tested according to the FMI Cross Check Rules.

Figure 5: Beginning of list of tools supporting FMI (source <https://www.fmi-standard.org>, status 11/08/2013)

At first glance, it is disappointing that there are so many “orange” entries of exporting tools that have not yet provided test FMUs and of importing tools that have not yet published simulation results. On the other hand this makes it transparent that there are combinations of FMU-exporting and importing tools that are tested and other that are not. This is exactly what was intended with the FMI Cross Checking rules and helps the user to select tools that he can rely on.

Figure 6: Results of FMI Cross Checking, (source <https://www.fmi-standard.org>, status 11/8/2013)

For the tools that participate in FMI Cross Checking, detailed results are published on the FMI website, as depicted in Figure 6. Thus, FMI Cross Checking is very valuable for industrial users, as they are supported with information, which combinations of exporting and importing tools have already

been tested successfully for some applications. FMI Cross Checking is a source to detect improvement potential of the simulation tools.

## 4 Proposed next steps

The actions that we have seen until now address mainly the problem classes II to IV. In order to address “real-life problems”, FMI Cross Checking should be extended to more tools and for multiple FMUs. The (co-)simulation techniques for importing tools should be improved and the improvements of FMI 2.0 should be implemented soon.

### 4.1 Extension of FMI Cross Check Rules

There should be more exported test FMUs provided by much more exporting tools and much more results of importing tools be published. FMI Cross Checking should be extended to *connected FMUs*. These FMUs could come from different exporting tools.

A simple test case is shown in Figure 7: An electrical motor with a gear and load torque (plant model) with PI controller (model of the software). The plant model and the control model are created in different MODELICA based simulation tools, then (separately) exported as FMUs and re-imported in different tools. This is a simple test example for a closed loop control, where the control software FMU might come from a different source than the plant model FMU. In some cases this worked already well from the beginning (2012), in other cases bugs have been fixed.

Figure 7: Example of connected FMUs exported from a MODELICA model

Further test examples of connected FMUs should be provided, e.g.,

- a stiff mechanical system consisting of various spring and damper elements exported as several FMUs, or
- a hybrid powertrain containing of different FMUs:
  - Simple map-based model of a combustion engine,
  - mechanical powertrain with gears and clutches,
  - electrical machine,
  - power electronics, and
  - control software model for the electrical machine.

Figure 8: Focus of FMI 2.x, FMU Compliance Checker and extended FMI Cross Checking

### 4.2 Extension of test cases to multiple connected FMUs

In order to test multiple connected FMUs in different tools easily a standardized file format for the definition of the set-up is proposed. This file should contain the following information:

- Simulation settings (e.g., simulation duration),
- list of the included FMUs,
- parameters of the included FMUs, and
- list of connections (i.e., which output of an FMU is connected to which input of another FMU).

Such a file should be preferably implemented as an XML file. All stimuli can also be defined in FMUs or provided as CSV file, as it is already possible for single FMUs within cross-checking. All files for a particular test should be either provided in a ZIP-file or a directory. With the help of such a standardized file describing the connections of multiple FMUs, the testing of connected FMUs can be done automatically in batch runs.

### 4.3 Improvement of (co-)simulation techniques of importing tools

New co-simulation techniques and master algorithms are proposed in the scientific community, see e.g. [13-15]. These new methods will improve co-simulation techniques. Also for model exchange new solver techniques should be developed that can handle multi-rate systems divided in several FMUs. The (co-)simulation capabilities of the importing tools for multiple FMUs can be compared by extended FMI Cross Checking.

### 4.4 Improvements of the FMI standard with FMI 2.0

Problem class I is addressed by bug fixes of the FMI standard. Maturity issues of the FMI standard 1.0 are not considered problematic, but additionally to new features, there will be some minor inconsistencies eliminated. FMI Cross Checking is an integral part of the introduction phase of FMI standard 2.0. Hence, it is expected that possible problems in the standard (problem class I) and the implementations (problem classes II to IV) will be detected at an early stage. FMI standard 2.0 will be only released, when a significant number of test implementations are available.

## 5 Outlook

### 5.1 Usage of FMI at Bosch

FMI enables the exchange of models between tools where this either had not been possible in the past or only by proprietary exchange formats (resulting in some cases in additional license fees). Additionally, FMI could replace existing in-house solutions of tool couplings and co-simulation. The use of a widely accepted standard is much more effective than developing and maintaining special interfaces.

### 5.2 FMI-based collaboration with OEMs

One motivation of support FMI is the increasing demand to exchange simulation models between OEM and suppliers [10]. While FMI as a technical standard is right on track, there are other points to be addressed such as model exchange process and accompanying documentation. This is developed in the ProSTEP Smart Systems Engineering Project (SSE) [6] in cooperation with OEMs. The main question there is how collaborative simulation-based engineering based on FMI can work. FMI is the best

available approach for tool-independent model exchange and co-simulation. FMI Compliance Checking and FMI Cross Checking address technical problems that existed in the past. FMI Cross checking should be extended to more complicated examples and also with multiple FMUs. Then, FMI can become the technical basis for model-based collaborative engineering in a heterogeneous tool environment with different partners.

# An FMI-Based Tool for Robust Design of Dynamical Systems

Maria Henningsson, Johan Åkesson, Hubertus Tummescheit  
Modelon AB / Modelon Inc.

## Abstract

Concepts from quality sciences, such as robust design, six-sigma, and design-of-experiments have had a large impact on product development in industry. These concepts are increasingly used in a model-based engineering context where data is gathered from simulation models rather than laboratory setups or prototypes.

This paper presents a framework to apply such ideas to analysis of dynamical systems. A set of tools that can be used for uncertainty analysis of dynamical Modelica models is presented. These tools are made available in the FMI Toolbox for MATLAB. The workflow and tools are demonstrated on a cooling loop design problem.

*Keywords:* *Design-of-experiments, Robust design, Controls, Modelica, FMI*

## 1 Introduction

Model-based engineering is a key technology for competitive product development. However, implementing, parameterizing, and validating simulation models of physical systems is time-consuming and costly. To make modeling efforts pay off, it is necessary to systematically consider tools, practices, and workflows to get the most use out of a model portfolio.

In this paper, we present a tool-chain and a methodology to efficiently integrate concepts from robust design and design-of-experiments to design and analysis of dynamical systems. Robust design is a well-established methodology that aims to design products and systems such that they are inherently robust to variations in components and operating conditions. A large amount of research has been directed towards robust design methodologies, that includes concepts such as design of experiments, quality engineering, critical parameter management, and six sigma [8, 5]. In the last years, there has been a growing interest in applying these kinds of techniques to analyze detailed simulation models, see e.g. [1, 2, 6, 7, 10, 4].

The tools presented in the paper are integrated into the FMI toolbox for MATLAB. Functional Mockup Interface (FMI) is a standard that allows importing and exporting dynamical models between different tools. First released in 2010, the standard has quickly been adopted in industry and is currently supported by a large range of tools used for physical systems modeling. FMI is a powerful standard for deploying tool-independent workflows and processes. Together with physical dynamical simulation models from Modelica, it provides a suitable platform for applying robust design concepts to analysis of dynamical systems.

The paper starts by discussing typical applications of simulation models, and providing an overview of design-of-experiments (DoE) concepts. The ideas behind the design of the new DoE tools in the FMI toolbox for MATLAB are then described. The use of the tools is then illustrated for the design of a cooling system, including both static analysis to size the components, and dynamic analysis to design a controller.

## 2 Applications of simulation models

Simulation model development represents a significant strategical investment in industries such as process, automotive, aerospace, and energy. Simulation models are, however, never an end in themselves but rather a means to answer questions in the engineering design process. Such questions may be:

- Hardware optimization: find dimensions, settings, and operating points for physical components
- Verification: check that performance meets specs in entire operating envelope
- Quality: check probabilistically that system specs are satisfied given tolerances on components
- Controls: design, analyze, and test control algorithms

Simulation models should ideally be developed such that they can provide answers to all of these questions. In the literature that address model-based engineering, it is interesting to note that there is a substantial cultural difference between research publications in the control community compared to the first three items in the list.

Robust design methodologies generally consider coarse large-scale mathematical and statistical models of complex systems. The models may be based on data from physical experiments or supplier spec sheets, and are generally steady-state [10]. The literature is heavily focused on processes, workflows, and tools.

Control engineering literature has a strong mathematical and analytical focus. Dynamics are central, and simplified mathematical model classes are analyzed with rigor. Much research is focused on mathematical analysis but there is surprisingly little written on processes and practices for control design in the product development process. It is commonly noted that there is a significant gap between much of the mathematically-oriented control research community and industrial practice.

In practice, control design is often based on linearization at a single operating point. For the design to be successful, this operating point needs to be representative of the dynamics across the operating range. It is normally difficult to know how the dynamics of the process vary with operating points and parameter uncertainty. Control design methods that go beyond linear models are often cumbersome to use and require a detailed understanding of which nonlinear effects or other process uncertainty that will be relevant. In-depth domain experience or trial-and-error is generally needed to find these dominant effects.

In practice, PID controllers based on simple experiments or linearized models are widely applied in industry, even though all real-world processes have some amount of nonlinearity or uncertainty. It is not uncommon to find controllers that perform poorly, with slow responses or oscillations at off-design operating conditions.

In this paper, we suggest how approaches from the robust design field can be applied to analysis of dynamical simulation models and control design. In order to use information on process nonlinearities and uncertainty in control design, it is imperative that tools be designed so that the relevant information can be extracted in a convenient and intuitive format.

### 3 Design-of-experiments

The term design-of-experiments (DoE) denotes methodologies to gather information from a system or process in a systematic way. Originally, it was introduced as a means to collect statistically sound experimental data sets for establishing cause-and-effects relationships.

In recent years, there has been an increasing interest in applying DoE techniques to extract data from simulation models [2, 1].

#### 3.1 Terminology and designs

In the DoE terminology, a *factor* denotes a quantity that is to be varied in the data set. An *experiment* is the procedure of testing the system with a particular choice of factor settings. A *response* is an outcome that is measured in the experiment. A *test matrix* is a list of factor setting combinations to be tested.

Selecting an appropriate test matrix is key to design-of-experiments. Figure 1 shows examples of possible test matrices in two dimensions. The first plot to the left shows a design based on one-factor-at-a-time (OFAT). Here, a nominal operating point is chosen, and off-nominal behavior is checked by varying one factor at a time. This is generally not an effective way to gather information on the system, since no interactions between the variables are considered. Nevertheless, this approach is often applied in an ad-hoc manner to test robustness.

The second plot shows a full-factorial test matrix design. This is equivalent to a multi-dimensional grid, where two or more different levels are chosen for each factor and the test matrix is then assembled from all combinations of the different levels. This method may work well in two dimensions but scales poorly with the number of factors. Other designs that are still based on fixed factor levels but that only select a subset of combinations are often preferred. Examples of such designs are fractional factorial designs, Box-Behnken designs, or central composite designs.

When DoE is applied to physical experiments, it can be advantageous to use a limited set of levels for each factor. For example, each different value of the factor could involve building a separate prototype. In simulation models, however, these constraints are generally not present and the test matrix can be constructed by spreading the test points freely in the ranges of interest. Monte-Carlo simulations spread the test points according to statistical distributions of the factors, which allows to get statistical estimates on distributions of

Figure 1: Example of test designs in two dimensions. OFAT = one-factor-at-a-time, FF = full factorial. Each of the four examples contain 100 test points.

the estimates. The third plot in Fig. 1 shows points that have been randomly sampled from uniform independent distributions for  $x_1$  and  $x_2$ .

To maximize the information that can be extracted from the process in a limited number of simulations, the points should fill the space spanned by the factors. Quasi-Monte Carlo designs use space-filling algorithms to spread the test points in a way that covers the space better than random sampling. The right-most plot in Fig. 1 shows a DoE design based on the Sobol space-filling algorithm. The advantages of using space-filling QMC designs instead of random sampling can be substantial in higher dimensions where corner-cases are poorly covered by random sampling [3].

### 3.2 Meta-models

The results of a DoE experiment consist of a list of pairs of factor values and response values  $\{x_i, y_i\}_{i=1..N}$  where  $N$  is the number of experiments. In some cases, it may be sufficient to verify that all  $y_i$  fulfill specifications, or to pick one  $x_i$  that give the desired outcome of the response. Often, however, we are interested in finding a factor combination  $x^*$  in a continuous set  $\mathcal{X}$  that optimizes some criteria defined by  $x$  and  $y$ . That is, it is necessary to interpolate between the points in the test matrix. To do that, some regularity on the map from  $x$  to  $y$  is assumed.

One way to find  $x^*$  is to perform sequential DoE in refined factor ranges close to the expected optimum. To limit the number of required experiments, it is generally better to use the existing data to generate a *meta-model* of the mapping from  $x$  to  $y$ . A meta-model is a simple empirical model that is obtained by fitting the data to some generic model structure, e.g. using linear regression, splines, neural networks or gaussian processes. Meta-models may also be referred to as surrogate models or emulators.

The role of meta-models is to replace the real sys-

tem with a simpler representation for analysis such as optimization or verification.

## 4 FMI tools for dynamical systems DoE

### 4.1 Modelica and FMI as a platform

Modelica has several attractive features as a platform for robust design of dynamical systems. Modelica component models normally have a sufficient level of detail to study influence of component variability, while still being simple enough to run large batches of experiments. From the nonlinear DAE models, information on the effect of both design parameters, operating conditions, and actuator settings can be investigated.

The FMI standard provides increased flexibility when model development and model analysis can be separated to different tools. The strengths of different tools and the skills engineering teams have developed using specific tools can be put to use more efficiently than if each tool needs to provide features for each potential modeling application. This facilitates cross-team use of the same model portfolio for different purposes.

MATLAB/Simulink is widely used as an environment for control design and implementation, and is thus a natural tool for analysis of model dynamics.

### 4.2 Tool requirements

The objective of a Modelica-based DoE tool is to remove the hurdles that make engineers resort to ad-hoc one-factor-at-a-time robustness testing.

The user wants to get a general sense of how sensitive the system is to parametric uncertainty. To do this, the user should be in charge of problem formulation, and provide the following input:

Figure 2: Workflow

- FMU model to be used
- FMU parameters, inputs, and outputs that are factors in the DoE
- Ranges or distributions for FMU parameters
- Number of experiments in the test matrix
- Type of DoE design
- Response variables to analyze or visualize

From this information, the tools should handle the back-end work:

- Construct a test matrix based on the desired DoE design and factor ranges or distributions
- Set FMU parameters
- Simulate the FMU at all points in test matrix, finding steady-state
- If the user specifies values for FMU outputs, find inputs that give these outputs
- Catching errors so that an entire batch of results is not wasted by a single test point that failed to simulate
- Linearizing the system at all points in the test matrix
- Provide convenient methods to visualize the results
- Construct suitable meta-models for analysis

### 4.3 DoE features in the FMI toolbox for MATLAB

The DoE tools in the FMI toolbox for MATLAB were introduced in release 1.6 with the purpose to make it easy and intuitive to perform DoE batch experiments on FMU models. The workflow is summarized in Fig. 2. The user specifies the names and distributions of DoE factors in either an Excel spreadsheet or a MATLAB file.

A class, `FMUDoESetup` holds the information on the FMU model to be simulated, the factor distributions, and simulation options. A batch of experiments is run by calling methods of `FMUDoESetup` that correspond to different DoE designs: full factorial, Sobol-sequence based, or Monte Carlo random simulation. There is also a possibility to use a custom test matrix. The DoE factors can be both FMU parameters, FMU inputs, or FMU outputs. If outputs are defined as factors, an equivalent number of inputs must be defined as 'free' inputs with min- max- and nominal values. These inputs are then optimized iteratively to obtain the specified outputs at each test point.

These methods return an object of the class `FMUDoEResult` that stores experiment results, including input-, output-, and state data, simulation status, and linearization at all test points. Data can be visualized by calling methods of the `FMUDoEResult` class to plot the main effects between the factors and responses, or to generate Bode diagrams or step responses for the ensemble of linearized systems at all test points.

In the future, support for meta-models may be added. An interesting application of meta-models generated from the DoE is to provide simplified subsystem models that can be used as a substitute for the full Modelica subsystem model in simulations of larger systems.

Figure 4: Result of screening design

fulfill the specs have a high pump speed, a high radiator gas flow, and a high heat exchanger efficiency.

The next step is to zoom in the design variables to a narrower range to find appropriate component specifications that meet the subsystem specification on engine-out coolant temperature. The DoE setup for this sizing task is given in Table 2. A new set of uniformly distributed test points in the new factor ranges was generated, and the effects on coolant temperature are shown in Fig. 5.

Table 2: Experiment setup for sizing the system

variable	dist	min	max	value
Q_flow [W]	constant			1e5
T_ambient [K]	constant			318.15
N_pump [rpm]	uniform	800	1200	
mflow_gas [kg/s]	uniform	2	4	
efficiency	uniform	0.6	0.8	

From Fig. 5, we can now decide on a set of component specs on the pump and radiator that would meet subsystem specification. This would normally involve a trade-off between cost and availability of components. We will here choose the design

$$\begin{aligned}
 N_{pump}^{max} &= 650 \text{ rpm} \\
 \eta &\geq 0.65 \\
 m_{flow} &\geq 3 \text{ kg/s}
 \end{aligned} \tag{1}$$

At worst-case conditions in terms of heat load and ambient temperature, this design gives  $T_{coolant} = 96.8^\circ\text{C}$ .

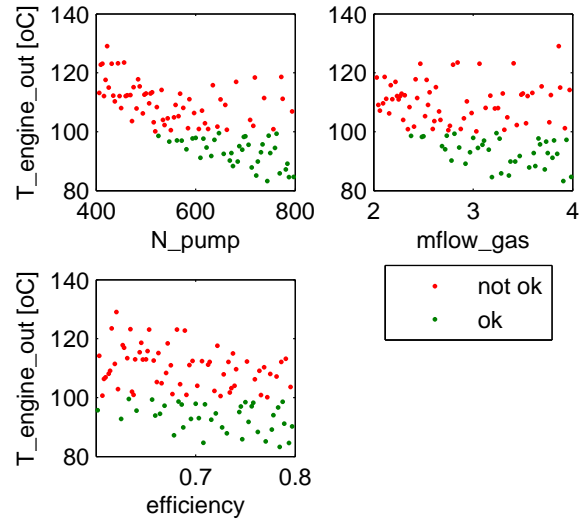

Figure 5: Result of sizing experiments

### 5.3 Dynamics

In the next step, we examine the dynamic response from pump speed command to engine-out coolant temperature. The DoE factor setup is given in Table 3. The factors were chosen to represent a range of operating conditions for the system.

Figure 6 shows the Bode diagram of the linearized systems at each point in the test matrix. It can be seen that the system is nonlinear: there is a large difference in the frequency response at different operating points.

We can now investigate the influence of the DoE factors on the dynamic response. Figure 7 shows the influence of the DoE factors on the steady-state gain of the linearized systems. The pump speed is the factor that has the largest influence on the steady-state gain.

### 5.4 Control design

The Bode diagram for the ensemble of linearizations in Fig. 6 can be used to design linear controllers that will have sufficient phase margins at all linearization points.

For nonlinear systems, there are no general guarantees that a controller that stabilizes each possible linearization will globally stabilize the closed-loop nonlinear system. In many cases, however, this is more of an academic concern. The alternative to looking at the ensemble of linearization may be to look at linearization in a single point. The ensemble of linearizations provides significantly more information.

A PI-controller with  $K = -50$  and  $T_i = 100$  was de-

## 6 Conclusions

We have presented tools and workflows to apply robust design methods to dynamical models. The tools are available in the FMI Toolbox for MATLAB. The aim in developing these tools has been to provide methods to work with parametric uncertainty in dynamical models in a lightweight and intuitive manner.

Each of the analysis and design steps in the cooling loop example involve less than ten MATLAB commands. By taking care of back-end work, the tools allow engineers to get answers from models in a systematic fashion rather than ad-hoc testing.

It would be interesting to see an increased academic focus on design process, tools, and workflows for control design. In this context, Modelica and the FMI standard provide a powerful platform.

## Abstract

The Functional Mockup Interface (FMI) standard enables hybrid simulation of models from different tools. Such tools can have different underlying behavioral semantics, creating challenges when models are combined. A case in point is the combination of the Rhapsody tool, widely used to describe and implement discrete control behavior, and Modelica, widely used to describe continuous plant behavior.

This paper describes a plugin we developed for exporting Functional Mockup Units (FMUs) from Rhapsody, and the results of combining generated FMUs with continuous models. When a Rhapsody FMU is used in a different environment, some basic assumptions on its behavior are challenged. We describe the semantic mismatches between the tools, to what extent they can be overcome, and what modelers need to do in order to preserve the intended semantics of an exported FMU.

**Keywords:** *FMI, Rhapsody, SysML, Hybrid simulation*

## 1 Motivation and Overview

Complex cyber-physical systems are composed out of components and subcomponents, often designed and manufactured by different organizations. Each component can come from a wide range of different engineering domains, including mechanical, electrical, control, and software. Each engineering domain uses its own languages and tools; these are often not integrated with each other. This makes it difficult to perform analysis, verification, and design-space exploration at the model level, resulting in errors that are discovered late in the process (typically during integration), and are expensive to fix.

In some cases there is ad-hoc integration between a pair of tools; for example, organizations commonly create connections using ad-hoc scripts. However, this is expensive, brittle, and sometimes wrong. Func-

tional Mockup Interface (FMI)<sup>1</sup> is an open international standard for the integration of models between different tools that may use different underlying semantics (e.g., discrete state machines and differential algebraic equations). It specifies an interface that encapsulates a model as a *Functional Mockup Unit (FMU)*, for communicating with hosting tools. The standard defines two types of export: *model exchange* and *co-simulation*. The main difference between them is that the former uses a solver of the hosting tool, while the latter includes its own solver and the hosting tool only orchestrates the simulation (transfers variables values, orders FMUs invocation, and selects the next communication step size).

SysML<sup>2</sup> and UML<sup>3</sup> are modeling languages standardized by the OMG to describe structure and behavior of systems at various levels of abstraction. Statecharts [6] are a popular formalism for specifying behavior in SysML and UML; they are an extension of finite-state machines, and enable very concise descriptions of finite-state models. They are used to describe reactive systems at a wide range of abstraction, from the details of embedded controllers to high-level manufacturing processes. Some tools, such as IBM Rational Rhapsody®,<sup>4</sup> can execute statechart models, and, in the case of software applications, to synthesize production code from these models. Model execution (sometimes called “simulation”) can be used to analyze and verify the design.

However, many modern systems are cyber-physical and include physical models whose behavior is modeled in other languages and tools. In the example of Section 2, a statechart is used to model the controller of a heating system; other aspects of the system, such as the thermal plant, sensors, and actua-

<sup>3</sup><http://www.uml.org>.

<sup>4</sup><http://www-03.ibm.com/software/products/en/ratirhapfami>.

tors, are modeled in Modelica®.<sup>5</sup> In order to simulate the whole system, it is therefore necessary to combine the discrete-event simulation of the statechart model in Rhapsody with the continuous dynamics described in Modelica. This paper describes the way in which an FMU that encapsulates the statechart can be exported from Rhapsody and used inside FMI-compliant tools.<sup>6</sup>

In Section 3 we analyze the semantic differences between the behavior of a SysML block in Rhapsody and that of the exported FMU. We highlight subtle, but in some cases significant differences. The naive expectation is for two communicating statecharts from the same Rhapsody model to retain their behavior when each is exported as an FMU and composed in the same way in a hosting tool. Because of the different conceptual semantics of Rhapsody statecharts and the FMI standard, this is very challenging. It follows that designers of SysML models that participate in hybrid simulations as FMUs need to be aware of this and design appropriately. We present a set of guidelines in Section 3.6.

## 2 Example

This section presents an example of a hybrid model, in which a controller specified as a statechart is exported as an FMU and used in a Modelica model. Figure 1 shows a Modelica model of a heater<sup>7</sup> in the SimulationX tool.<sup>8</sup> The model consists of the heater plant (bottom), a temperature sensor (displayed as a thermometer), a controller (top, in black) that receives the sensor input and a parameter specifying the desired temperature, and two actuators that can turn on or off two heating elements (lower left, in blue). A switch (labeled “booleanStep1” in the middle of the diagram) turns the heating system on or off.

The plant is specified in Modelica using a set of differential algebraic equations, and the sensor and actuators are also simple Modelica models. The controller, however, is specified as a SysML statechart in Rhapsody; it is shown in Figure 2. The controller starts in state OFF; it moves to ON when the switch signal changes to true, and moves back when it changes to false.

In state ON, the controller keeps track of the num-

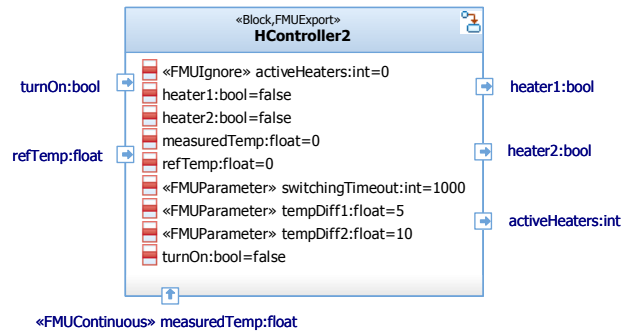

Figure 3: The interface of the controller block.

ber of active heaters (between 0 and 2); in the initial sub-state, NoHeating, this is set to zero, and both heaters are turned off. Each of the three states has a timeout transition (labeled  $tm(\text{switchingTimeout})$ ), it is used to sample the temperature sensor periodically. The operation  $tempDiff()$  returns the difference between the reference temperature (provided as the top input in Figure 1) and the measured temperature (bottom input). The model has two parameters,  $tempDiff1$  and  $tempDiff2$ . Whenever the temperature difference is more than  $tempDiff1$ , the first heater is turned on; if the difference exceeds  $tempDiff2$ , both heaters are turned on. This is achieved by the transitions between the states, which check the temperature difference. These transitions have just a condition (specified in brackets) but no trigger. They are checked each time the state is entered; that is, periodically whenever the timeout expires.

The interface of the controller is a SysML *block*, shown in Figure 3. It has three inputs, which are SysML *flow ports*: the boolean-valued  $turnOn$ , for the on/off switch, and two float-valued input ports, one for the reference temperature, and one for the measured temperature. The last is annotated with the stereotype «FMUContinuous» to indicate that it is a continuous input; by default, inputs are assumed to be discrete (see Section 3.5). Each flow port is associated with a block attribute of the same name (shown inside the block); each of these has an associated initial value. The block has three output flow ports: the first two are boolean-valued signals that turn the heaters on and off, and the third is an integer-valued signal that carries the number of currently active heaters. In addition, the block has three parameters, for the switching timeout and the temperature thresholds.

Figure 4 shows the essential parts of the model description in the FMU generated by the plugin from this block. It starts with a type definition describing the float type associated with the block’s inputs. Since

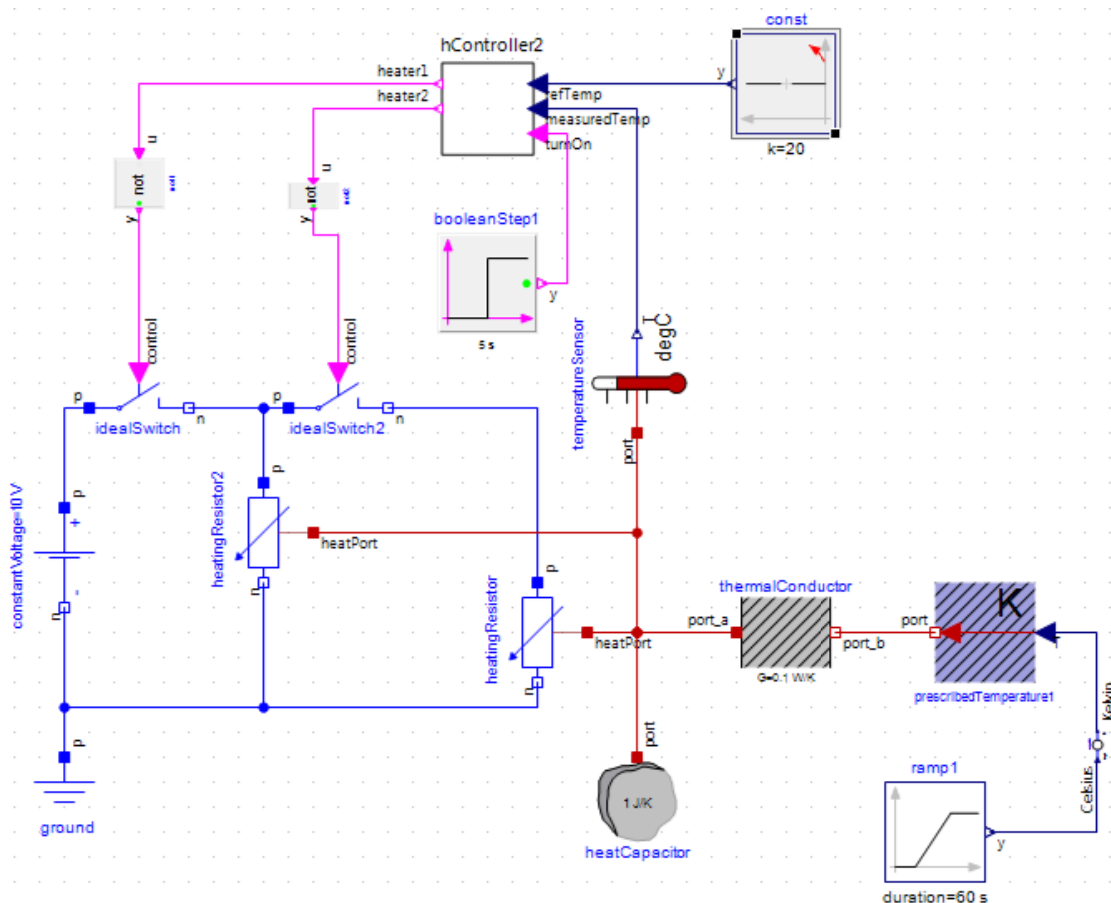

Figure 1: The heater model in SimulationX.

this type defines single-precision floating-point numbers, while the FMI standard defines real numbers using double precision, it is translated into an FMI real type with a constrained range. Following the type definition are the specifications of the model variables. First are the three inputs, the first with a boolean type and the others with the constrained type. All inputs have input causality and discrete variability, except for `measuredTemp`, which is continuous. Following those are the two output booleans, and the three parameters.

In order to let the plugin know how to treat the various block elements, we defined a UML profile containing a set of stereotypes. For example, the «FMUParameter» stereotype denotes the three block attributes that are to be treated as parameters (Figure 3). The signal `activeHeaters` is not exported to the FMU, as indicated by the stereotype «FMIIgnore» annotating the block attribute of the same name. The model of Figure 1 defines how these inputs and outputs are connected to the rest of the model when the exported FMU is imported into the SimulationX environment. Inside SimulationX, the imported FMUs are represented as regular Modelica blocks, so they can be naturally in-

cluded in any Modelica model.

Figure 5 shows the results of the simulation using the exported controller FMU in SimulationX. The top graph shows the `ramp1` variable from the block at the

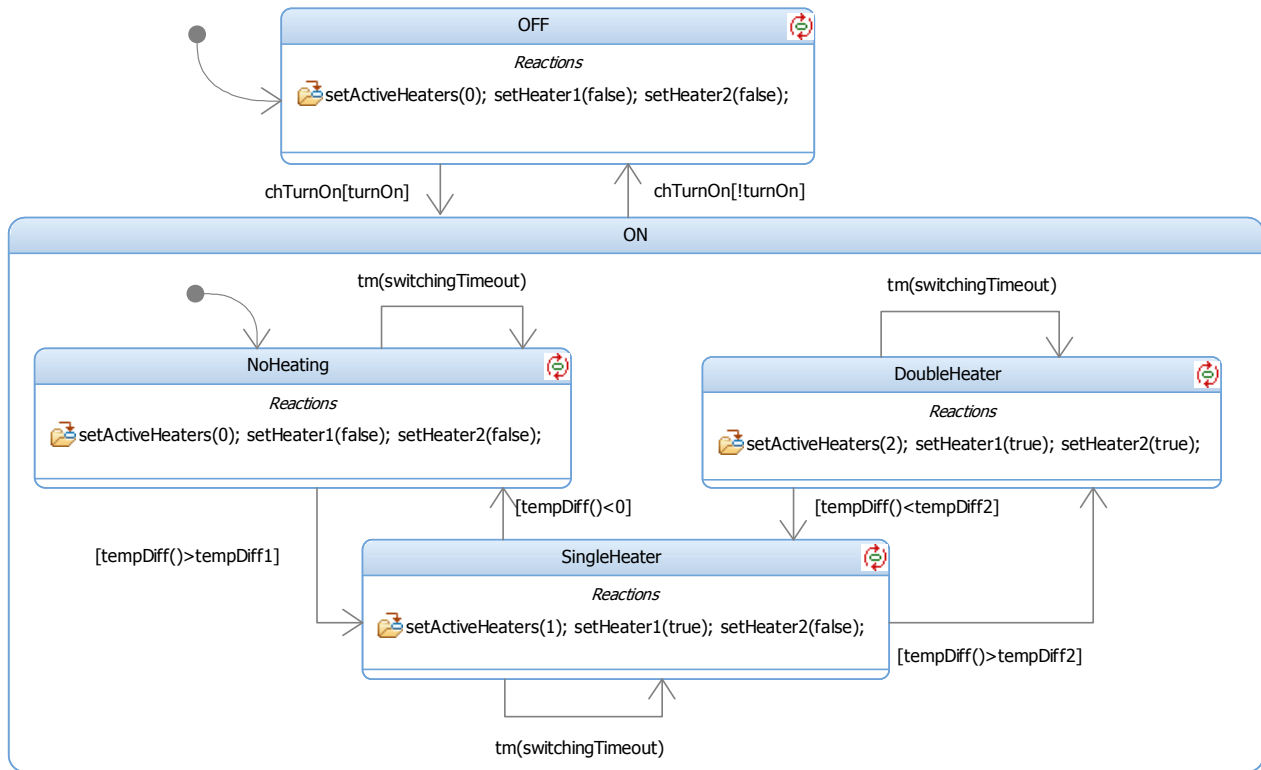

Figure 2: The heater controller in Rhapsody.

top right of Figure 1; this variable represents the ambient temperature, which starts at 0 and climbs to 20 degrees during the second minute. The second graph shows the on/off switch, which is turned on 5 seconds after the simulation starts. The next two graphs show the signals that the controller sends to activate the heaters. When the switch is initially turned on, the measured temperature is zero, and both heaters are activated. The second heater is deactivated after a few seconds, while the first heater is turned on and off according to the measured temperature. The bottom graph shows the values measured by the temperature sensor; the value climbs from 0 to a little over 20 degrees, then seesaws as a result of the activation of the heaters. Toward the end of the second minute, once the ambient temperature is high enough, both heaters are turned off, and the sensed temperature climbs slowly, as expected.

### 3 FMI for SysML

This section describes the FMU export functionality we developed for Rhapsody as a plugin, and discusses the design decisions and their implications. The FMI standard defines two export modes: *model exchange* and *co-simulation*. The major difference be-

tween them is that model exchange requires a hosting tool to provide an ordinary differential equation (ODE) solver to perform the simulation, and therefore the models need to expose all internal equations. Rhapsody models are discrete and do not need an ODE solver, so co-simulation would be appropriate; this in turn could enable the use of the FMU in environments that do not provide ODE solvers. Unfortunately, FMI for co-simulation cannot handle discrete events efficiently [2]. For example, the co-simulation API, unlike the model exchange API, does not provide a way to report the next event time. We have therefore chosen to use the model-exchange mode for our plugin. In any case, most of the points discussed in this paper apply to co-simulation as well.

The elements of the SysML block that are exported are currently limited to atomic flow ports and attributes. As we saw in the example, input flow ports of the SysML block are exposed as inputs of the FMU, and output flow ports become outputs. Values of attributes of the block that have corresponding flow ports are considered by Rhapsody as storage for the values of the ports, and are therefore represented by the same input or output variables. Other attributes will become FMI discrete internal variables; if they are annotated with «FMUParameter», they will become FMI parameters. Initial values of attributes will be translated into

Figure 4: The modelDescription.xml file of the generated FMU (excerpt).

a start value of the corresponding FMU variable. However, the «FMUIgnore» stereotype will prevent any element from being exposed. This gives the user fine control over what parts of the block are to be exposed externally.

Not all SysML elements are currently supported. In particular, the following are challenging, because of mismatches between SysML and the FMI standard:

- Bi-directional flow ports, since the FMI standard does not allow variables that are both inputs and outputs. This restriction may be lifted in future, by artificially creating two variables, one for each direction of a bi-directional port. However, there are various issues such as naming of ports and variables, and synchronizing the values of the input and output variables correctly.
- SysML standard ports, since they carry SysML events (these are not to be confused with FMI

events), which are not supported by the FMI standard.

The FMU export functionality is based on the FMU SDK provided by QTronic,<sup>9</sup> which provides a skeleton implementation of the FMI API. The implementation of the exported FMU consists of the code normally generated by Rhapsody for the block, with an additional wrapper that adapts it to the requirements of the FMI standard. The FMU export process consists of the main steps described in Algorithm 1.

The first step collects the various elements to be exposed according to the rules described above; it also checks for illegal or unsupported combinations and reports them to the user (such reports can be suppressed by using the «FMUIgnore» stereotype). The second step creates the modelDescription.xml file, which describes the interface of the generated FMU.

<sup>9</sup><http://www.qtronic.de/en/fmusdk.html>.

**Algorithm 1** Generate FMU Wrapper

1. Analyze the SysML model to identify input and output ports and internal variables, discover and report errors.
2. Generate the FMU model description file.
3. Apply the standard Rhapsody code generation.
4. Generate the code for the FMU wrapper.
5. Compile and package the FMU.

**Algorithm 2** fmiEventUpdate

1. Set Rhapsody time based on the time received in the last fmiSetTime call.
2. Set the block's input variables based on the previous set of fmiSetXXX calls.
3. Invoke the Rhapsody-generated code to execute a behavioral step.
4. Update the wrapper's variables corresponding to the FMU outputs.
5. Set the next event time to the earliest timeout active in the block.

The third step invokes Rhapsody's code-generation facilities to create the implementation of the behavior of the block to be exported. The fourth step creates the code that adapts Rhapsody's implementation to the FMI standard. This wrapper code is discussed in most of the rest of this section. Finally, the code is compiled and packaged in the .fmu file.

### 3.1 The FMU Wrapper

The FMU Wrapper generated in step 4 of the FMU export algorithm supports the FMI interface (currently version 1.0 for Model Exchange) and translates it to the Rhapsody interface. The wrapper keeps a set of variables corresponding to the FMU variables, together with a set of other internal variables (for example, the current simulation time). Most of the FMI functions are implemented by reading or setting these variables; the real work is done by the fmiEventUpdate function. The wrapper algorithm implements this function as described by Algorithm 2.

This algorithm seems quite straightforward, but it

hides many subtle semantic issues. When a block is exported as an FMU, its behavior can be changed by the way that the hosting tool delivers variable changes to the wrapper, using the FMI interface calls, and by the way that the wrapper handles these calls. While the former is out of the control of the Rhapsody FMU export plugin, the latter behavior is, and there are a number of different ways to create the wrapper, each of which yields somewhat different semantics. There are two issues that need to be addressed. The first is communication: the way inputs are transferred to the FMU and outputs are received from it. The second is scheduling: when communication takes place, and how much activity the FMU encapsulating the SysML block allows the block to perform before it considers the step to be completed.

Ideally, Rhapsody blocks exported as FMUs would retain their behavioral semantics, and blocks written without consideration for their context could be used as FMUs. At the very least, the naive expectation could be that if two or more Rhapsody blocks are exported as FMUs out of the same model, and are connected in the hosting environment in exactly the same way they were connected in the Rhapsody model, their behavior will not change. However, context does matter, in simulation as well as in physical realizations. Full preservation of semantics between two exported blocks is challenging; see Section 3.2. In the context of non-Rhapsody models, the different semantics of the FMI standard and of Rhapsody create other difficulties, as discussed in Sections 3.3–3.5.

### 3.2 Quoted Out of Context

In this section we consider the case of two blocks from a single Rhapsody model, both of which are exported as FMUs, and connected in the external tool in the same way as they were in the original model. How does the implementation of the wrapper change the semantics of the joint model?

The Rhapsody semantics [7] describes the behavior of a statechart as consisting of a series of steps; each step may consist of several state changes, and may produce several variable-change and other events. There is a strict order between these events.

Changing the value of a SysML flow port in Rhapsody might also create an internal change event (such as chTurnOn in Figure 2); this event can trigger one or more transitions. The value of the attribute corresponding to the port is changed immediately. However, all events in Rhapsody are sent asynchronously; events sent to each port (from whatever source) are

queued, and delivered in order. In particular, updating several variables consecutively creates one event for each, and these are handled one by one. The order is therefore significant; the block may perform arbitrary actions in response to each event; for example, a typical response to an event is for the statechart to move to a new state. Such actions can change how the block responds to the next event.

As mentioned above, the FMI standard allows changing any number of variables in a single event-processing cycle, and the changes are semantically simultaneous. This is a consequence of the synchronous semantics on which the FMI standard is based. A Rhapsody block can perform a sequence of discrete changes in response to a single event. For example, a single transition might include a series of actions that sequentially change a number of outputs. This implies that, in order to ensure that the order of the corresponding Rhapsody events is preserved, these discrete changes must be delivered one by one to the FMU interface. However, this could cause an inconsistency between the values, if several related variables (such as current and resistance) are not changed simultaneously.

The wrapper can implement this strategy by ending step 3 of Algorithm 2 inside each of the setter functions for the output variables in the Rhapsody-generated code, and continuing with steps 4–5. In the next event-processing cycle, the wrapper would allow Rhapsody to continue from the point it was stopped. All of these events, except for the last one, will require another event-iteration cycle by returning `fmiFalse` in the `interactionConverged` field of the return value of the `fmiEventUpdate` function; this does not advance the simulation time.

This strategy allows other FMUs to generate new inputs after each output is reported. These inputs can be delivered by the wrapper to Rhapsody immediately; that would be consistent with the Rhapsody semantics, since it represents an execution of the Rhapsody model in which each block is run in a separate thread and output generation happens to be fully synchronized between threads. However, Rhapsody semantics allows other behaviors; for example, those where one thread is significantly faster than the others.

In this strategy, the exported FMU behaves in accordance with the original semantics of the SysML blocks in Rhapsody. Any strategy that batches consecutive outputs may violate the semantics, since the generated FMU can be used in a context in which the order of these output updates is significant. However,

as mentioned above, the Rhapsody semantics may expose inconsistent value. Furthermore, this strategy could potentially be very inefficient, forcing the whole simulation to receive and react to each discrete change separately. Because of these issues, the current implementation of the FMU wrapper delivers all variable-change events simultaneously; the modeler of the SysML block should be aware of this and introduce small delays between sequential changes when the order is important. This strategy takes the other extreme, in that it allows the block to perform all its possible behavior in a single cycle, and only stops when it reaches a wait for some timeout or event.

A related issue is the treatment of multiple changes to the same variable. In the example, the command to turn the first heater on is given by the signal `heater1`; the command is recognized when the signal changes value from `false` to `true`. It is possible that some path in the statechart contains a series of transitions in the same step, containing the action `setVar(false)` followed by `setVar(true)`. In Rhapsody, both actions will be communicated to the connected element, resulting in two changes in the value of the signal, with two corresponding change events, causing the command to be recognized. However, if this signal is exported as an FMU output, the behavior will depend on how the wrapper treats multiple changes to the same variable. In the implemented version of the wrapper, the second change will override the first, causing the signal to retain its previous value without change. The other block will therefore receive only the last value update, which contains the variable's original value; this might result in different behavior.

In the other strategy, both changes will be delivered separately, and the command will be recognized. A third scheduling strategy, in the middle between these two extremes, is to present changes to different variables together, as in the implemented version, but separate changes to the same variable. This can be done by having the wrapper divide the stream of events received from Rhapsody into segments, each starting with a change to a variable that already has another change in a previous segment. All the events in a single segment will be presented at once, but different segments will be presented separately.

On input (step 2 of Algorithm 2), the wrapper must be ready to accept simultaneous changes of discrete variables, even if it only produces them one at a time, since inputs may be provided by other types of FMUs. There are a number of ways to treat multiple such events. The first is for the wrapper to issue the events

Table 1: Two behaviors of the rounding strategy.

FMI Time ( <i>sec.</i> )	Rhapsody Time ( <i>msec.</i> )	$x_1$	$x_2$	$x_3$	$y$
Scenario 1					
0.0000	0	1	2	3	2
0.0050	5	-1	2	3	2
0.0100	10	1	2	3	2
Scenario 2					
0.0000	0	1	2	3	2
0.0050	5	-1	2	3	2
0.0096	10	-1	2	-3	-2
0.0100	10	1	2	3	-2

to Rhapsody in an arbitrary order, and require modelers of SysML blocks to be exported to ensure that the order does not matter; this is the option currently taken by the plugin. A second option is to impose a specific order on the events; this order can be specified by a SysML stereotype.

### 3.3 A Question of Time

In the current FMI standard, time is measured as a double-precision floating-point value in units of seconds, whereas in Rhapsody time is represented as an integer, in units of milliseconds. This mismatch is another cause for semantic incompatibilities. (The same problem would exist even if the standard used integral units at a different time resolution, such as microseconds.) How should the FMU wrapper handle `fmiSetTime` calls that set the time between two Rhapsody clock ticks?

Of course, a perfect match of the time-lines is impossible. An obvious candidate strategy is to round times to the nearest integral value. However, this strategy causes strange phenomena, where the addition of an unrelated `fmiEventUpdate` call can completely change the behavior. For example, consider a SysML block with three discrete inputs,  $x_1$ ,  $x_2$ , and  $x_3$ , and one discrete output,  $y$ . The behavior of the block is very simple; periodically every 10 milliseconds, it updates  $y$  to be either  $x_2$  or  $-x_2$ , depending on whether  $x_1 > 0$  or not. Input  $x_3$  is not used at all and should not influence this behavior in any way.

Table 1 displays two possible behaviors of this block, under the rounding strategy. In the first scenario,  $y$  is updated at time 0.0, and again at time 0.01. The change of  $x_1$  at time 0.005 does not update the value of  $y$ , since the block is still waiting for its timeout. The second scenario starts in the same way, except that at FMI time 0.0096, variable  $x_3$  gets a new

value. Because this time is rounded to Rhapsody time 10, the block is activated and updates the value of  $y$ . When  $x_1$  is changed back to 1 at FMI time 0.01, the block is already waiting for its next timeout, at (Rhapsody) time 20, and  $y$  is not updated again. The result is a different value for  $y$ , due to a spurious update of  $x_3$ . For continuous systems, due to numerical issues, such differences might be acceptable. For discrete system, working at precise clocks, however, this type of behavior is obviously unacceptable.

Because of this issue, the FMU export plugin uses truncation rather than rounding. With truncation, such undesirable behaviors cannot occur, since intermediate event updates such as the one in the example will not trigger the FMU's timeout and will not advance its internal clock. In the example, FMI time 0.0096 will be translated to Rhapsody time 9, will not trigger the timeout transition, and will not change the value of  $y$ .

It is common in continuous systems to consider a discrete unit of time strictly as a sampling interval, by ignoring all changes that occur between two sampling points except for the last one. However, this approach can result in counterintuitive behavior for discrete models; for example, a slight shift in the timing of a discrete signal change can cause it to be ignored.

### 3.4 Types

A Rhapsody model can employ the full type system of the target language (which, in this paper, we consider to be C). The FMI standard defines a different set of types; these only contain scalar types (real, integer, boolean, string, and enumeration). Each of these can be customized; for example, real and integer types can have an associated range, as shown in the type definition of Figure 4. The FMU export plugin attempts to define the closest possible FMI type for the C type used in the block. Obviously, integral C types are expressed as FMI integers, and floating-point types (`float`, `double`) as FMI reals. Ranges are applied in the FMI types based on the ranges of the C types; however, not all types can be accurately represented in this way. For example, in the 32-bit FMI platform, `fmiInteger` is defined as a C `int`; this means that the C type `unsigned int` has a wider range than that admitted by an FMI integer, which is always signed.

### 3.5 Discrete or Continuous?

Rhapsody is based on a discrete-time model; triggers for transitions between states are all discrete events, and variables are modified in a discrete way (that is,

signals are piecewise constant). Modelers in Rhapsody therefore think of all variables as discrete. However, when a Rhapsody FMU is used in a hybrid model, some of its inputs may be connected to continuous signals. This places restrictions on the way such inputs may be used in the statechart.

Transitions in a statechart are activated by *triggers*, which are discrete events. Triggers include variable-update events (such as `chTurnOn` in Figure 2, which signals a change in the `turnOn` input). The time of a change event for a continuous variable is not well defined, because at a call of `fmiEventUpdate` all FMI variables are updated, whether relevant or not (as in the second scenario of Table 1). This can cause the behavior of the statechart to become unpredictable. Modelers must therefore avoid change events for continuous inputs. The use of continuous inputs in other places is not restricted. For example, checking the value of an input in a transition guard (such as `tempDiff() < 0`) does not cause a problem, even if the input is continuous, since the guard is only evaluated at timeout events. The same holds for using a continuous input in an action.

### 3.6 Guidelines for Exportable Blocks

Based on the previous discussion, the following points should be considered when designing a Rhapsody model to be exported as an FMU. First, change events must not be used for continuous signals, although their values can be freely used otherwise. Second, if the order of changes in output variables is important, non-zero delay should be introduced between changes. Third, non-zero delay should be introduced between changes of the same variable if all intermediate values need to be observed. Finally, to preserve communication semantics between Rhapsody blocks or include features that are not yet supported by the FMU export functionality, the composition of the blocks should be exported as a single FMU.

## 4 Related work

Modeling and simulation of hybrid systems is an active research topic [5, 3]. Carloni et al. [4] provide a detailed analysis and comparison of the semantics of commonly-used tools. They conclude that there is a strong need to allow integration of different tools, and suggest leveraging the Hybrid Systems Interchange Format (HSIF) to mediate model semantics between tools. This approach is very different from

the FMI code-generation-based approach used in our work, since FMI is mainly focused on the standardization of a model execution API, and exposes only the model information required for this purpose (for example, whether variables are discrete or continuous, and dependencies between variables).

Other interesting approaches for integrating SysML and Modelica are based on extensions of SysML such as the SysML-Modelica Transformation standard,<sup>10</sup> or of ModelicaML [10] where Modelica could be described using the UML profile extension mechanism. Specifically, Schamai et al. [11] suggest a formal approach to modeling UML statecharts using Modelica, and highlight various semantic differences. For example, in ModelicaML, all available events are processed in parallel in the next evaluation of the state machine, while in Rhapsody statechart events are queued and processed in order according to the UML run-to-completion semantics [7].

In practice, changing languages or tools is a major undertaking, and users are reluctant to do so. Our work therefore concentrates on using the popular Rhapsody tool in new contexts. As discussed in Section 3, this requires some attention to modeling details that might differ in other contexts, but there is no need to change the tool itself. This is similar to the approach taken by Sakairi et al. [9] to integrate Rhapsody and Simulink®, except that they use a proprietary S-function interface.<sup>11</sup> Because we use the FMI standard, our approach is not limited to integration with a single tool or language, but can work with any FMI-complaint simulator.

Pohlmann et al. [8] export FMUs for MechatronicUML [1] instead of Rhapsody SysML. They do not describe any semantic differences between MechatronicUML and the generated FMU. They do say that “a discrete port implements an array of message queues,” since communication in MechatronicUML is asynchronous; it seems, therefore, that the same issues described in Section 3.2 are relevant there as well.

## 5 Conclusions

The FMI standard can be used for hybrid simulation of systems modeled using several tools. We described the Rhapsody plugin that exports FMUs encapsulating SysML blocks whose behavior is defined using statecharts, and demonstrated it on an example that

<sup>10</sup><http://www.omg.org/spec/SyM/1.0>.

<sup>11</sup><http://www.mathworks.com/help/simulink/sfg/what-is-an-s-function.html>.

combines the SysML model with a Modelica model. We highlighted subtle but important semantic differences between Rhapsody and FMI, causing the compositional behavior of the FMUs to differ from that of the original blocks, and provided guidelines that will prevent such behavioral differences. Since different tools come with their own semantics, we expect that such mismatches are common, especially when connecting continuous-time with discrete models, and that our guidelines will generalize to many such cases.

## Acknowledgments

We are grateful to Sergey Zolotnitsky for his help with the implementation of the plugin. We thank ITI GmbH for their assistance with SimulationX.

## Abstract

In this paper we propose a method how to automatically utilize continuous-time Modelica models directly in nonlinear state estimators. The approach is based on an extended FMI 2.0 Co-Simulation Interface [1] that interacts with the state estimation algorithms implemented in a Modelica library [2]. Besides a short introduction to Kalman Filter based state estimation, we give details on a generic interface to cooperate with FMUs in Modelica, an implementation of nonlinear state estimation based on this interface, and the Dymola prototype used for the evaluation. Finally we show first results in a tire load estimation application [3] for DLR's robotic electric research platform ROMO [4].

*Keywords: FMI 2.0 Co-Simulation, FMU, Inline Integration, Kalman Filter, State Estimation, Moving Horizon Estimation, Tire Load Estimation*

## 1 Introduction

With the raise of computational power in the last decades the possibilities to implement complex control strategies in real world applications enhanced tremendously. For most of them a good knowledge of the actual states is necessary. Often these are not directly measurable due to cost limitations or missing sensors (for example, it is not practical to measure in-tire forces). In the ITEA2 project MODRIO [5] one aim is to develop state estimation technologies for plants that use the knowledge of complex models of the controlled system itself. These models are often designed, parameterized and optimized as multidomain models in Modelica. To re-use these models for estimation and control purposes the Functional Mockup Interface [1] turns out to be very useful. Three years ago, we presented a concept for state

estimation [2], [6] using FMI 1.0 Model Exchange [7], using Modelica function pointers to separate the prediction model from the observer algorithms and to create an easy reconfigurable framework for state estimation purposes. This approach had several limitations and difficulties that we want to overcome based on a slightly extended FMI 2.0 Co-Simulation Interface [1]. Furthermore we introduced a different way how the user interacts with the prediction model and the desired state estimation method.

One goal of the research performed in MODRIO is to build-up a complete tool chain so that an end-user can utilize a complex model in a state estimation algorithm and download the estimator to an embedded target. To our knowledge such tool chains are not available today. There are toolboxes available for the estimation algorithms, such as [8], [9], but it is non-trivial and time-consuming to utilize them for a concrete application with a nonlinear model and download the result to a real-time target.

The following sections are organized as follows. In Section 2 we briefly recap the well-known Extended Kalman Filter, Unscented Kalman Filter and the Moving Horizon estimator algorithms. From these descriptions we deduce the requirements on a generic interface for nonlinear models. Afterwards, Section 3 gives a closer look into the Modelica implementation, as well as a proposal for a user-friendly configuration interface. Moreover, we show how the FMI 2.0 Co-Simulation needs to be extended to fit the requirements of the prediction steps sketched in Section 2. As a use-case we show an automotive tire load estimation application [3] in Section 4. To validate this approach measurement data acquired with DLR's ROboMObil [4] are used.

## 2 Model Evaluations in State Estimation Algorithms

It is assumed that the plant model to be used in state estimation is naturally described as nonlinear continuous-time state space system:

$$\begin{aligned}\dot{\mathbf{x}} &= \mathbf{f}(\mathbf{x}, \mathbf{u}), \\ \mathbf{y} &= \mathbf{h}(\mathbf{x}),\end{aligned}\quad (1)$$

$$t \in \mathbb{R}, \mathbf{u}(t) \in \mathbb{R}^{n_u}, \mathbf{x}(t) \in \mathbb{R}^{n_x}, \mathbf{y}(t) \in \mathbb{R}^{n_y}$$

where  $t$  is time,  $\mathbf{u}(t)$  is the vector of inputs,  $\mathbf{x}(t)$  is the vector of states and  $\mathbf{y}(t)$  is the vector of outputs. Such a model shall be provided as a Functional Mockup Unit (FMU) [1]. In this paper plant models are defined in Modelica and exported as FMUs using Dymola. However, all the results are also valid if FMUs are generated by other tools and/or non-Modelica environments, as long as the FMU supports a slightly extended FMI 2.0 Co-Simulation Interface according to our proposal.

Model (1) cannot be utilized directly in a sampled data system. Instead a discrete-time representation is needed for use in a discrete-time state estimator. The following discrete-time version of (1) with additive Gaussian noise is used in the sequel:

$$\begin{aligned}\mathbf{x}_k &= \mathbf{f}_{k|k-1}(\mathbf{x}_{k-1}, \mathbf{u}_{k-1}) + \mathbf{w}_{k-1}, \\ \mathbf{y}_k &= \mathbf{h}(\mathbf{x}_k) + \mathbf{v}_k, \\ \mathbf{w}_k &\sim N(0, \mathbf{Q}_k), \\ \mathbf{v}_k &\sim N(0, \mathbf{R}_k).\end{aligned}\quad (2)$$

Here  $t_k$  is the  $k$ -th sample time instant of a periodically sampled data system,  $\mathbf{u}_k = \mathbf{u}(t_k)$ ,  $\mathbf{x}_k = \mathbf{x}(t_k)$ ,  $\mathbf{y}_k = \mathbf{y}(t_k)$ ,  $\mathbf{w}_k$ ,  $\mathbf{v}_k$  is Gaussian noise, and

$$\mathbf{f}_{k|k-1} = \mathbf{x}_{k-1} + \int_{t_{k-1}}^{t_k} \mathbf{f}(\mathbf{x}, \mathbf{u}_{k-1}) dt. \quad (3)$$

A tool chain has to support (3) because it is non-trivial to transform the natural description (1) in (2).

### 2.1 The Estimation Prediction Step

In this section, we briefly summarize the steps of Kalman Filter based state estimation and will then have a closer look to the prediction step (compare Figure 1) of the Extended Kalman Filter (EKF), the Unscented Kalman Filter (UKF), and a more complex Kalman Filter based algorithm the so-called Moving Horizon Estimation (MHE) [10]. Here the need of an efficient and reliable way for the feed forward model simulation rises tremendously. For further information regarding Kalman Filter techniques, see especially the standard textbook [11]. This section is based on [12], [11] and [2].

In Figure 1 a cycle flow diagram of a recursive Kalman Filter algorithm is depicted. The filter is initial-

ized with the initial state vector guess  $\hat{\mathbf{x}}_0^+$  and the initial guess of the state covariance matrix  $\mathbf{P}_0^+$ . These can be seen as a stochastic expectation for believe in the first guess of the estimation task.

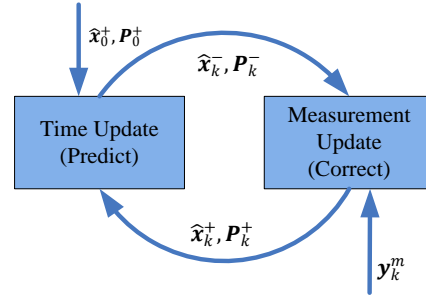

Figure 1: Principle of Kalman Filter based Estimation,  $\mathbf{y}_k^m$  denotes the vector of measured outputs

Afterwards the cycle of the two steps *Predict* and *Correct* begins and is executed with a predetermined static sample time  $T_s$ . The additive Gaussian noise assumption in Eq. (2) is handled by the tuning covariance matrices  $\mathbf{Q}, \mathbf{R}$ . These enable the user to tune the filter to the specific task. For nonlinear model state estimation the widely used EKF algorithm is given as pseudo code in Table 1.

Table 1: Extended Kalman Filter Algorithm

Initialization:

$$\begin{aligned}\hat{\mathbf{x}}_0^+ &= E(\mathbf{x}_0) \quad // \text{ expectation value} \\ \mathbf{P}_0^+ &= E((\mathbf{x}_0 - \hat{\mathbf{x}}_0^+)(\mathbf{x}_0 - \hat{\mathbf{x}}_0^+)^T)\end{aligned}$$

for  $k = 1, 2, \dots$ :

$$\text{Predict: } \hat{\mathbf{x}}_k^- = \mathbf{f}_{k|k-1}(\hat{\mathbf{x}}_{k-1}^+, \mathbf{u}_{k-1})$$

$$\mathbf{P}_k^- = \mathbf{F}_{k-1} \mathbf{P}_{k-1}^+ \mathbf{F}_{k-1}^T + \mathbf{Q}$$

$$\text{where } \mathbf{F}_{k-1} = e^{\left( \frac{\partial \mathbf{f}}{\partial \mathbf{x}} \right)_{\hat{\mathbf{x}}_{k-1}^+} \cdot T_s}$$

$$\text{Correct: } \mathbf{K}_k = \mathbf{P}_k^- \mathbf{H}_k^T \cdot (\mathbf{H}_k \mathbf{P}_k^- \mathbf{H}_k^T + \mathbf{R})^{-1}$$

$$\text{where } \mathbf{H}_k = \frac{\partial \mathbf{h}}{\partial \mathbf{x}} \Big|_{\hat{\mathbf{x}}_k^-}$$

$$\hat{\mathbf{x}}_k^+ = \hat{\mathbf{x}}_k^- + \mathbf{K}_k \cdot (\mathbf{y}_k^m - \mathbf{h}(\hat{\mathbf{x}}_k^-))$$

$$\mathbf{P}_k^+ = (\mathbf{I} - \mathbf{K}_k \cdot \mathbf{H}_k) \cdot \mathbf{P}_k^-$$

The red marked sections indicate where the evaluation of the underlying system model equations (2) is necessary. The calculation of  $\hat{\mathbf{x}}_k^-$  is performed by integrating model (1) from  $t_{k-1}$  to  $t_k$ .  $\mathbf{F}_{k-1}$  is the state-transitions matrix of  $\mathbf{f}$  with respect to  $\mathbf{x}$  at  $\hat{\mathbf{x}}_{k-1}^+$  and  $\mathbf{H}_k$  is the partial derivative matrix of  $\mathbf{h}$  with respect to  $\mathbf{x}$  at  $\hat{\mathbf{x}}_k^-$ . The Jacobians  $\mathbf{J}_{k-1}$  and  $\mathbf{H}_k$  must either be provided directly, or they can be determined numerically, for example with a forward difference quotient:

$$\text{for } i = 1, 2, \dots, n_x; \Delta \cong \sqrt{\epsilon_{ps}}$$

$$(\mathbf{J}_{k-1})_i = \frac{\mathbf{f}(\hat{\mathbf{x}}_{k-1} + \Delta \mathbf{e}_i, \mathbf{u}_{k-1}) - \mathbf{f}(\hat{\mathbf{x}}_{k-1}, \mathbf{u}_{k-1})}{\Delta} \quad (4)$$

## 2.2 UKF Sigma Point Approach

The so called *Sigma Point Transformation* is based on the idea that it is easier to approximate a Gaussian distribution, than it is to approximate an arbitrary nonlinear function or transformation [13], [11]. The parts of the UKF algorithm, where model evaluations are necessary, are given in Table 2. The selection of the *Sigma Points* in matrix  $X$  is performed via a static scaling factor  $\gamma(n, \alpha, \kappa)$  and the matrix square root of the a posteriori covariance matrix. The number of states is denoted by  $n = n_x$ ,  $\alpha$  is the spread around the last state value  $\hat{x}_{k-1}^+$  and  $\kappa$  is a parameter for the stochastic distribution assumption. In total  $2n + 1$  points must be created and then used as initial values for  $2n + 1$  simulations from  $t_{k-1}$  to  $t_k$  to compute  $X_{k|k-1}$ .

Table 2: UKF Prediction Step

$$\begin{aligned}
 X_{k-1} &= \left[ \hat{x}_{k-1}, \hat{X}_{k-1} + \gamma \sqrt{P_{k-1}^+}, \hat{X}_{k-1} - \gamma \sqrt{P_{k-1}^+} \right] \\
 X_{k|k-1} &= f_{k|k-1}(X_{k-1}, u_{k-1}) \\
 \hat{x}_k^- &= \sum_{i=0}^{2n} w_i^m \cdot X_{k|k-1,i} \\
 P_k^- &= \sum_{i=0}^{2n} w_i^c \cdot (X_{k|k-1,i} - \hat{x}_k^-)(X_{k|k-1,i} - \hat{x}_k^-)^T + Q \\
 X_k' &= [\hat{x}_k^-, \hat{X}_k^- + \gamma \sqrt{P_k^-}, \hat{X}_k^- - \gamma \sqrt{P_k^-}] \\
 Y_k &= h(X_k') \\
 \hat{y}_k^- &= \sum_{i=0}^{2n} w_i^m \cdot Y_{k,i}
 \end{aligned}$$

The predicted values  $\hat{x}_k^-$ ,  $\hat{y}_k^-$ ,  $P_k^-$  are calculated via weighted sums with the predetermined weights  $w_i^{c,m}(n, \alpha, \kappa)$ . We define  $\hat{X} := [\hat{x}, \hat{x}, \dots, \hat{x}] \in \mathbb{R}^{n \times n}$  and in our notation a vector depending function (e.g.  $f_{k|k-1}$  or  $h$ ) with a matrix argument returns a matrix with columns that are equal to the evaluated columns of the matrix argument.

It can be shown that the nonlinear approximation accuracy of the UKF is minimum twice higher compared to an EKF. This becomes important in case of strong nonlinearities in the prediction model (for a detailed proof see [14] – Appendix A).

## 2.3 MHE with NLG Method

The *Moving Horizon Estimator* (MHE) is very closely connected to *Model Predictive Control* (MPC). Instead of predicting future control inputs we have a sliding window (with  $M$  steps to the past) that moves every  $T_s$  one step ahead. Therefore, all past  $M$  measurements are taken into account.

Figure 2: Moving window in MHE application

In this way the estimate gets more robust against external disturbances, delayed measurements can be incorporated and also constraints can be imposed directly [10]. Neglecting the last two points, the optimization objective can be written as follows:

Table 3: MHE Optimization Objective

$$\begin{aligned}
 &\min_{\xi_k} c(\xi_k) \\
 &\xi_k = (x_{k-M}^T, x_{k-M+1}^T, \dots, x_k^T)^T \\
 &x_{int,k-M} = \hat{x}_{k-M}^+ \\
 &x_{int,i} = f_{i|i-1}(x_{int,i-1}, u_{i-1}) \quad (i = k-M+1, \dots, k) \\
 &c(\xi_k) = \|x_{k-M} - \hat{x}_{k-M}^+\|_{I_{k-M}^+}^2 \\
 &+ \sum_{i=k-M}^k \|y_i^m - h(x_i)\|_{R^{-1}}^2 + \sum_{i=k-M+1}^k \|x_i - x_{int,i}\|_{Q^{-1}}^2
 \end{aligned}$$

The initial constraint (first line in definition of  $c(\xi_k)$ ) is calculated via a Kalman Filter step i.e. an EKF from Table 1, wherein the information matrix  $I_{k-M}^+ = (P_{k-M}^+)^{-1}$ .

For its solution a *Nonlinear Decent Search* (NLG) is useful, because only the first derivatives of the system functions are needed, which is an important constraint for the available interfaces of FMI 2.0 (compare [1]). The algorithm of the unconstrained NLG is given in Table 4, for details please see [15]:

Table 4: MHE Optimization Algorithm

1. Set  $j = 0$  and define  $\xi_k^0 = (x_{int,k-M}^T, \dots, x_{int,k}^T)^T$
2. Decent direction:
 
$$r_j = -\nabla c(\xi_k^j)$$
3. Line search to determine the step size:
 
$$\eta_j = \underset{0 \leq \eta}{\operatorname{argmin}} c(\xi_k^j + \eta \cdot r_j)$$
4. Optimization step:
 
$$\xi_k^{j+1} = \xi_k^j + \eta_j r_j$$
5. If stop criterion not reached:  
 $j = j + 1$  and go to step 2;

In step 1 an initial solution  $\xi_k^0$  is needed. A good approach for its calculation is the open loop integration of the prediction model from  $x_{k-M}$  to  $x_k$ . The gradi-

ent  $\nabla c(\xi_k^j)$  of the decent direction can be calculated as shown in Table 5 (again, all parts that need a model evaluation are marked in red).

Table 5: MHE Gradient Calculation

$$\begin{aligned} \mathbf{R}^* &= (\mathbf{R} \cdot \mathbf{R})^{-1}; \mathbf{Q}^* = (\mathbf{Q} \cdot \mathbf{Q})^{-1} \\ \nabla c_{1:n} &= (\mathbf{I}_{k-M}^+ + (\mathbf{I}_{k-M}^+)^T)(\mathbf{x}_{k-M} - \hat{\mathbf{x}}_{k-M}^+) \\ &\quad - 2 \frac{\partial \mathbf{h}(\mathbf{x}_{k-M})^T}{\partial \mathbf{x}_{k-M}} \mathbf{R}^* (\mathbf{y}_{k-M}^m - \mathbf{h}(\mathbf{x}_{k-M})) \\ \text{for } i &= k - M + 1, \dots, k: \\ \nabla c_{1+(i-k+M):n:(i-k+M+1):n} &= \frac{\partial c(\xi_k)}{\partial \mathbf{x}_i} \\ &= 2 \mathbf{Q}^* (\mathbf{x}_i - \mathbf{x}_{int,i}) - 2 \frac{\partial \mathbf{h}(\mathbf{x}_i)^T}{\partial \mathbf{x}_i} \mathbf{R}^* (\mathbf{y}_i^m - \mathbf{h}(\mathbf{x}_i)) \end{aligned}$$

## 2.4 Summary of Needed Model Evaluations

In Table 6 all needed evaluations of the prediction model (compare Eq. (1), (2)) for state estimation applications are summarized. A tool chain has to provide these model evaluations. In the right column the name of the Modelica function is listed to trigger the corresponding evaluation in the tool chain proposed by this article, for details see section 3.3.

Table 6: Model evaluations for nonlinear state estimation (in the right column the name of the Modelica functions are defined to trigger the evaluations in the tool chain proposed in this article, see section 3.3).

Required model evaluations		Modelica
Integration between two sample points:	$\mathbf{f}_{k k-1} = \mathbf{x}_{k-1} + \int_{t_{k-1}}^{t_k} \mathbf{f}(\mathbf{x}, \mathbf{u}_{k-1}) dt$	integrator
Derivative evaluation:	$\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}, \mathbf{u})$	f
Output evaluation:	$\mathbf{y} = \mathbf{h}(\mathbf{x})$	h
<b>Optional model evaluations</b> (if not provided, computed numerically by difference quotients)		
State Jacobian matrix:	$\frac{\partial \mathbf{f}}{\partial \mathbf{x}}(\mathbf{x}, \mathbf{u})$	fx
Output Jacobian matrix:	$\frac{\partial \mathbf{h}}{\partial \mathbf{x}}(\mathbf{x})$	hx

## 3 Nonlinear Kalman Filters and FMI

In Section 2 different state estimation algorithms are summarized. The goal of this paper is to provide a tool chain for nonlinear state estimation based on the

model equations of a Modelica model. In [2] it is explained why a pure Modelica solution to reach this goal is currently not possible. Using FMI helps to overcome this situation. In [2] we concentrated on FMI 1.0 for Model Exchange with the drawback that the integration algorithm for performing prediction steps of a Kalman Filter has to be implemented in Modelica, a non-trivial task. FMI 2.0 for Co-Simulation [1] simplifies the implementation significantly because the integration algorithm, including event handling, is embedded inside the FMU. Still some features are missing. In a Dymola prototype these have been added in order that the “required” functions from Table 6 are supported.

The overall process of using a state estimator in Modelica is illustrated in Figure 3:

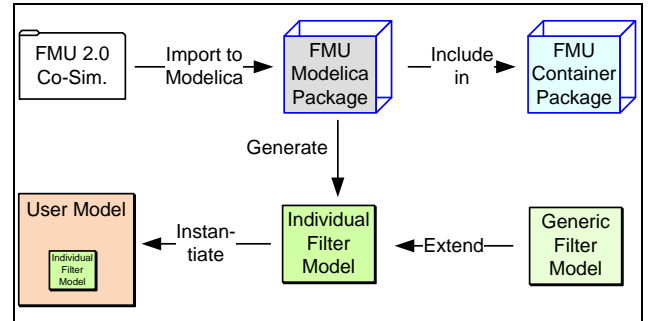

Figure 3: Process flow to generate a state estimator based on an FMU

An FMU (usually exported from a Modelica model) is imported into the Modelica environment by extending the package `FMUImportTemplate`. The imported package can be included in an FMU container package to collect several FMUs for easy access. For such an FMU package an *Individual Kalman Filter* model is generated that provides variable names on buses and user convenient parameter menus. The algorithmic part of the state estimation is provided in a *Generic Filter Model*. Finally, the individual filter model can be instantiated in the user’s application model. An example is shown in the next figure:

Figure 4: Instance of an individual EKF Kalman filter model generated by the process from Figure 3. The bus on the left side contains the individual input and measurement variables of the FMU and the bus on the right side contains the individual estimated state and output variables of the FMU.

In the following sub-sections, the details of the process from Figure 3 are described.

### 3.1 FMI for State Estimation with Dymola

The standard FMI Co-Simulation Interface allows integrating (1) from sample instant  $t_{k-1}$  to  $t_k$  with function `fmiDoStep(..)` and therefore computing (2). In standard co-simulation the continuous-time states of a model are hidden in the co-simulation slave. However, for state estimation the states need to be explicit and it must be possible to reset the states at sample instants, see Section 2. In order to achieve this, Dymola 2014 FD01, that has already support for FMI 2.0 Co-Simulation according to [1], has been extended in a prototype with the needed features. Especially,

- the continuous-time states are reported in the `modelDescription.xml` file under element `ModelStructure`,
- it is possible to explicitly set the continuous-time states with `fmiSetReal(..)` before `fmiDoStep(..)` is called,
- it is possible to inquire the actual values of all variables with `fmiGetReal(..)` after `fmiSetReal(..)` was called, without an `fmiDoStep(..)` in between,
- when importing an FMU for Co-Simulation in to Modelica, Dymola generates the Modelica code optionally according to the `FMUImportTemplate` package shown in the next section. This package serves as interface to access the needed FMI functionality from a Modelica model or function.

### 3.2 FMUImportTemplate package

Importing an FMU means to generate a package that contains all the functionality needed to simulate the FMU or use it in a state estimator. For this the template package `FMUImportTemplate` is provided, see code and figure below. The imported FMU extends from the `FMUImportTemplate` and redeclares all elements.

```
partial package FMUImportTemplate
  constant Integer nx=1;
  ...
  constant Integer id_x[nx];
  ...
  constant String stateNames[nx];
  ...
  replaceable model SimulationModel
  end SimulationModel;

  replaceable model InitializationModel
    fmiModel fmi;
    parameter Real fmiInitOk(fixed=false);
  end InitializationModel;
```

```
replaceable partial class fmiModel
  extends ExternalObject;
  function constructor
  ...
  end constructor;
...
end fmiModel;

replaceable function fmiDoStep
  input fmiModel fmi;
  ...
  end fmiDoStep;
...
end FMUImportTemplate;
```

Important dimensions of the FMU such as the number of continuous states `nx`, inputs `nu` and outputs `ny` are set in the imported FMU package. Furthermore, the FMI references are available by the vectors `id_x`, `id_dx`, `id_u` and `id_y` for state, state derivative, input and output variables. It is also important to get variable names for states, inputs and outputs. Otherwise the order of the components in the vectors `x`, `u`, `y` would be only visible by user-unfriendly reference values instead of variable names. The names are used in the parameter GUIs of the filter model in the next subsection and in the input and output bus of a filter model.

The imported FMU package contains two models: `SimulationModel` and `InitializationModel`. The model `SimulationModel` is a fully operating Modelica model (with inputs and outputs) that wraps the FMU for Co-Simulation whereas in `InitializationModel` only the FMU is instantiated by the external object `fmiModel` and the FMI initialization phase is executed. The `InitializationModel` is used in a Kalman Filter model; the `SimulationModel` is contained for completeness to use the imported FMU package also for other applications like a “real” FMU for Co-Simulation in the Modelica simulation environment.

The FMU package provides interface functions to all (or at least most) of the functions defined in

the FMI Co-Simulation standard 2.0. For a user-convenient handling of the FMU import process, it is desirable to import an FMU as a sub-package into an existing Modelica package. The default package is the package FMUContainer that hosts several imported FMUs, see figure above.

### 3.3 Model Functions for State Estimators

The state estimator algorithms are implemented with Modelica functions that provide the needed model evaluations. In partial package BaseFunctions the interfaces of these functions are defined and in package SystemFunctions the function prototypes are collected. The latter are replaceable functions that provide the needed functionality of Table 6 (the right column of this table lists the name of the function).

For example, partial function fBase is defined as:

```
partial function fBase "Base class of the
    state equation  $dx/dt = f(x,u,t)$ "
  input Integer nx "Number of states";
  input Integer nu "Number of inputs";
  input Real x[nx] "States";
  input Real u[nu] "Inputs";
  input Modelica.SIunits.Time t "Time";
  output Real dxdt[nx] "Derivatives";
end fBase;
```

The dimensions  $nx$ ,  $nu$  are conceptually not necessary, because the dimensions could be determined by the size of the vectors  $x$  and  $u$ . Currently, Dymola does not support arrays with non-fixed sizes in function calls of translated Modelica models. The function prototypes are collected in package SystemFunctions:

```
partial package SystemFunctions
  replaceable function f
    extends fBase;
  end f;
  ...
  replaceable function integrator
    extends integratorBase;
  end integrator;
end SystemFunctions;
```

For a particular model, an implementation of the SystemFunctions functions has to be provided. For FMUs, this is performed with the generic package FMISystemFunctions. The implementation is based on the FMUImportTemplate package and holds therefore for every FMU that extends from this template package.

```
package FMISystemFunctions
  extends SystemFunctions;
  replaceable package FMU
    constrainedby FMUImportTemplate;
  redeclare function extends f
    input FMU.fmiModel fmi;
  algorithm
    FMU.fmiSetReal(fmi, FMU.id_u, u);
    FMU.fmiSetReal(fmi, FMU.id_x, x);
    dxdt := FMU.fmiGetReal(fmi, FMU.id_dx);
  end f;
  ...
  redeclare function extends integrator
    input FMU.fmiModel fmi;
  algorithm
    FMU.fmiSaveFMUState(fmi);
    FMU.fmiSetReal(fmi, FMU.id_u, u);
    FMU.fmiSetReal(fmi, FMU.id_x, x);
    FMU.fmiDoStep(fmi, t, dt, 0);
    xNew := FMU.fmiGetReal(fmi, FMU.id_x);
    FMU.fmiRestoreFMUState(fmi);
  end integrator;
end FMISystemFunctions;
```

The system functions  $f$ ,  $h$ ,  $integrator$  can be directly implemented with functions provided in FMUImportTemplate. The Jacobians  $fx$  and  $hx$  are implemented by computing them numerically with finite difference quotients. Once Dymola supports directional derivatives for imported FMUs for the extended Co-Simulation case, that is function  $fmiGetDirectionalDerivatives$ , then this function can be directly called and will provide a more efficient and reliable evaluation of the Jacobians.

The Dymola prototype supports two techniques for the FMI function  $fmiDoStep$ . Either the *Sundials* solvers [16] are used (that are integrators with variable step size and error control) to numerically integrate the model equations, or *Inline integration* [17] is applied, that means fixed step solvers are embedded in the model equations. The Kalman Filter library works with both techniques. For real-time applications, fixed-step methods have to be used and therefore a Kalman filter will usually utilize Inline integration.

The functions  $fmiSave/RestoreFMUState$  in the above code fragments are auxiliary functions that call the FMI functions  $fmiGet/Set/FreeFMUState$  to enable several calls of  $fmiDoStep$  starting at the same time instant, as needed, for example, for the UKF.

### 3.4 Tailored Kalman Filter Models in Modelica

Based on the imported FMU package an individual Kalman Filter model has to be generated. In the current version of the Kalman Filter Library this can be performed automatically by use of a Modelica/Dymola scripting function. The idea is to define an input bus  $InBus$  and an output bus  $OutBus$  for

exchanging variables between the filter model and higher level models. The names of the bus variables correspond to the variable names of the imported FMU – only “:”, “;”, “[”, “]” and “ ” are replaced by “\_” due to Modelica syntax. The bus definitions for the use-case example in Section 4 are listed below:

```
encapsulated expandable connector InBus
import Modelica;
extends Modelica.Icons.SignalBus;
// Model Inputs
Real u;
// Measured Model Outputs
Real accBody;
Real sRel;
Real accArmUp;
end InBus;

encapsulated expandable connector OutBus
import Modelica;
extends Modelica.Icons.SignalBus;
// Estimated Model States
Real mass_wheel_s;
Real mass_wheel_v;
Real mass_body_s;
Real mass_body_v;
Real ...FirstOrderShapingFilter_s;
// Estimated Model Outputs
Real accBody;
Real sRel;
Real accArmUp;
end OutBus;
```

The advantage of this approach is that not vectors of anonymous variables are defined, but bus variables with meaningful names tailored to each individual FMU. The main state estimation algorithms are implemented in sub-functions and in a partial filter model, e.g. for an UKF (see Section 2.2). This model defines several variables and parameters for the filter algorithm that is called at each sample point of a sampled integration time interval. In the filter model also an instance of `InitializationModel` of the imported FMU package is included. Together with the package `FMISystemFunction` all necessary parts are put together to run FMI based Kalman Filter algorithms within a Modelica model.

Figure 5: Parameter menu for output variances with names of output variables

A further improvement of the user interface compared to [2] are the filter parameters like state and

output variances that are shown in lists with names of the respective variables – instead of indices of vectors, see Figure 5. Basically, a matrix is defined and via Dymola specific annotations row and column headings can be added to the parameter menu. For example the menu in Figure 5 is defined in the following way:

```
parameter Real yData[FMUPackage.ny,1]
annotation(Dialog(
  __Dymola_columnHeadings =
    {"R[i,i] (outputVariance^2)"},
  __Dymola_rowHeadings =
    {"accBody", "sRel", "accArmUp"}));
```

In the parameter menu of the filter in Figure 6 the user can press the button on the right side of `yData` to get the menu of Figure 5. Also the model parameters of the FMU may be modified by clicking on the button on the right side of `ModelParameters`.

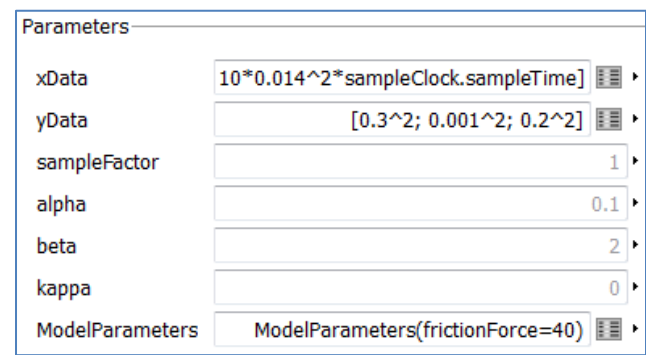

Figure 6: Menu of a UKF SR Kalman Filter model

## 4 Example: Vehicle Vertical Dynamics States Estimation

As an example application, the above described Kalman Filter Library is used to develop an advanced state estimator for the vertical dynamics of the ROboMObil. A more detailed version of this application case is available in [3]. This section is based on [3], but now the method and software from Section 3 are used. The ROboMObil is a robotic electric vehicle concept (see Figure 7) developed at the Robotics and Mechatronics Center of the German Aerospace Center DLR. It is comprised of four Wheel Robots (Figure 8 – left), which integrate traction motor, steering, brake system, spring and semi-active damper. Further details on the ROboMObil can be found in [4].

Figure 7: ROMO on the four-post test rig

In contrast to fully active suspension systems they need far less energy [19]. Therefore a diversity of control strategies for semi-active dampers is presented in literature. An overview about these control strategies can be found in [20] and [21]. As most of these strategies need state feedback, but not all states can be measured, state estimation becomes an important topic during the design of semi-active suspension systems.

Figure 8: Left: the “Wheel Robot” concept, right: nonlinear two mass system [3]

The DLR Kalman Filter Library as presented in Section 3 offers an easy to use framework for the development of state estimators for nonlinear systems like this semi-active suspension system. Especially a square root utilizing implementation of the UKF (Subsection 2.2) algorithm SR-UKF is well suited for highly nonlinear systems, because of its higher order linearization accuracy of mean and covariance. Furthermore the nonlinear parts can be taken into account more easily than in an EKF algorithm (Subsection. 2.1) since no derivatives and Jacobians are needed.

#### 4.1 The Nonlinear Quarter Vehicle Model

The suspension system of the Wheel Robot is modeled as a nonlinear two mass system (see Figure 8 – right) as described in [3]. The corresponding implementation in Modelica is shown in Figure 9. The model consists of the two masses *mass\_body* and *mass\_wheel*, a linear spring damper component, which approximates the wheel behavior, a road mod-

el as explained in [18] or [22] and the *body\_spring* and *body\_damper*.

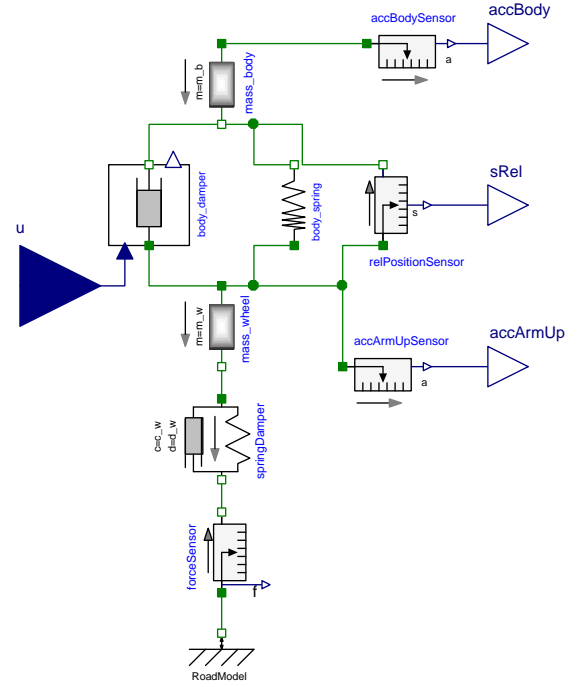

Figure 9: Nonlinear two mass system in Modelica

As the motion of these two components are connected to the wheel and body motion by a push rod-rocker kinematic (compare Figure 8 – left), the motion and the force of these components is scaled by a transmission ratio. Details on the nonlinear characteristic of the *body\_damper* are shown in [3].

The third main nonlinearity of the two mass system besides the transmission ratio and the damper characteristic is the friction of the suspension system. It covers the friction of the damper and of all joints of the suspension system. For the state estimation the friction force  $F_f$  is modeled without stiction by a smooth tanh-switching function:

$$F_f = F_{f,const} * \tanh(v_d/\epsilon_f). \quad (5)$$

Here  $F_{f,const}$  represents a constant sliding friction. The direction of the friction force is determined according to the current velocity difference  $v_d$  between body and wheel. The parameter  $\epsilon_f$  is used to define the transitional behavior of the tanh-function.

#### 4.2 Experimental Setup and Results

The nonlinear two mass system described in Section 4.1 is integrated in an SR-UKF state estimator using the DLR Kalman Library including the FMI 2.0 for Co-Simulation interface and Inline-integration as described in Section 3. Subsequently the resulting estimators are applied to the measurement data recorded with the ROboMObil on a four-post test rig. Figure 10 shows the Modelica model of the SR-UKF

estimator. On the left-hand side the measurement data is read by a *CombiTimeTable* and on the right-hand side the estimator, called *Filter*, and its corresponding settings block *observerControl* can be found. The estimator uses three measurement inputs: the acceleration of the body above the wheel, the wheel acceleration and the damper deflection.

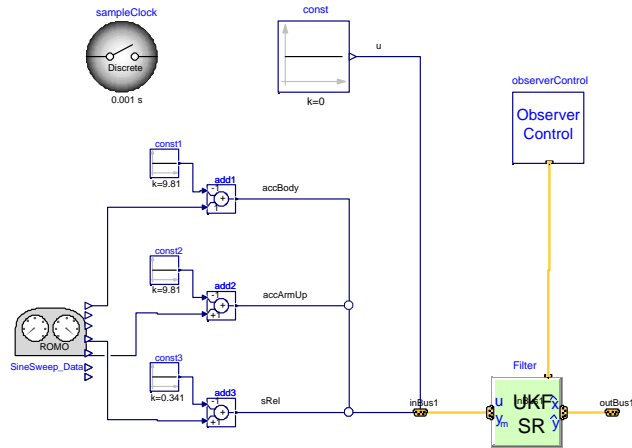

Figure 10: SR-UKF estimator in Modelica

The parameters of the estimators, as well as the system covariances, are tuned according to the optimization procedure presented in [3]. The measurement covariances are set according to the sensor noise. The experimental setup is shown in Figure 11.

The performance of the estimator, subject to a sine sweep excitation, is shown in Figure 11 by comparing the measured and the estimated tire contact forces in the last plot. Please notice that the tire force  $F_{z\_measure}$  is only available on the four-post test rig (Figure 7). It is used for validating the estimator performance and not as a measurement output  $y^m$  to it (compare experimental setup in Figure 10). Additionally the measurements are compared to the estimated measurements. It can be seen that the estimator reproduces the measurements and the tire contact force with a good accuracy.

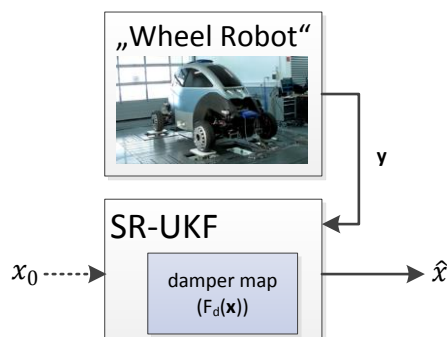

Figure 11: State estimator setup with measurement data from the four-post test rig

As the body accelerometer has the largest noise level, the weighting of its measurements *accBody* was chosen in such a way that the estimator relies more

on the damper deflection *sRel* and the wheel acceleration *accArmUp*.

Figure 12: Comparison of measurements to estimated measurement (plot 1-3) and contact force estimation (plot 4) on the four-post test rig – “sine sweep” excitation

## 5 Conclusions and Outlook

In this paper we have shown how the FMI 2.0 standard for Co-Simulation [1] can be extended to use its capabilities for modern state estimation problems. We discussed the parts of the different estimation algorithm in detail, the needed evaluation of the system functions and integration between two sample instants via the FMI interface. Furthermore, we gave implementation details on a user friendly workflow as well as a set of necessary Modelica models and functions. The use case example of our vertical dynamics state estimation [3] application for our ROboMobil [4] showed good results in accuracy and computational efficiency. As a next step we plan to test them on a commercial real-time platform for stability and deterministic execution.

## 6 Acknowledgement

This paper is based on research performed within the ITEA2 project MODRIO. Partial financial support of the German BMBF and the Swedish VINNOVA for this development are highly appreciated.

Furthermore, the authors would like to thank Bernhard Thiele from DLR for his support to implement and cross-compile FMUs on real-time hardware and Marcus Baur for his support in implementing Kalman Filter algorithms in Modelica.

## Abstract

To cope with demands for future low carbon society, development of new-type small electric vehicles (EVs) becomes very active. To reduce the energy consumption in various actual driving conditions, considering overall running resistance such as aerodynamic resistance, tire rolling resistance including cornering drag, mechanical and electrical losses, etc. will be necessary. On the other hand, to cope with reduced stability against external disturbances such as side wind because of the light weight, it was clarified that additional control of direct yaw moment is effective. In this paper, model-based development of a new electric vehicle using Modelica is described. Full vehicle model considering both vehicle dynamics and energy consumption was developed and utilized to investigate the best possible solutions for both basic design of the vehicle and design of the control system.

*Keywords: Future electric vehicles; Stability and Handling Performance; Energy Consumption*

## 1 Introduction

To cope with future mobility society, development of many new concept vehicles is increasingly active in recent years. Figure 1 shows a new EU regulation about light weight vehicles [1]. Those vehicles have characteristics of smaller size, lighter weight, less number of passengers than conventional vehicles. Also those vehicles tend to be equipped with lower RRC (Rolling Resistance Coefficients) tires and new driving systems mainly using electric motors to achieve less emission and less energy consumption. On the other hand, Toyota has a vision about future eco-cars as shown in Figure 2. Toyota thinks EVs are

suitable as short-distance mobility though there is a possibility of extending the driving range using range extender devices such as small combustion engine, additional battery and so on. In this paper, model-based-development of a new vehicle using Modelica is described. The models were developed based on Vehicle Dynamics Library (VDL) of Dymola.

Category & Category Name	Sub category & Sub category name	Example
L6e, Light quadricycle	L6Ae Light on-road quad	
	L6Be Light mini-car	
L7e, Heavy quadricycle	L7Ae Heavy on-road quad	
	L7Be Heavy mini-car	

Figure 1: New EU Regulation "Light-category vehicles" [1]

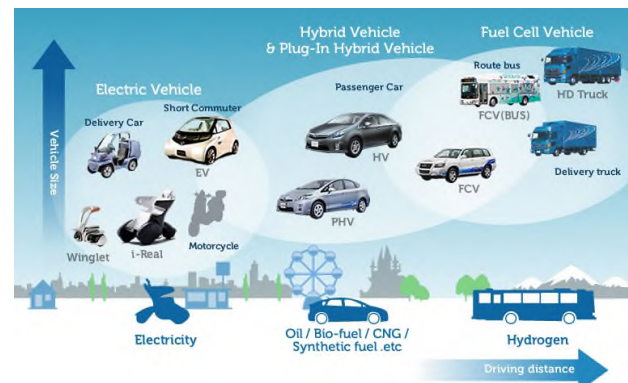

Figure 2: Toyota's scenario about future eco-cars

## 2 Modeling and simulation studies of the future vehicle

### 2.1 Target vehicle

Table 1: Specifications of the target vehicle

	Target plan	L7Be
Vehicle weight	< 600 kg	< 400* kg
Passengers	4	2
Max. Payload incl. passengers	300 kg	200 kg
Rated power	25 kW	< 15 kW
Max. speed	120 km/h	> 45 km/h
Driving range	> 100 km	-

(\* weight without batteries)

Table 1 shows comparison of specifications between our plan and EU regulation L7Be. Our aim is to develop a heavier and more powerful vehicle with more passengers than L7Be considering actual usefulness.

### 2.2 Simulation studies about basic specifications

To consider energy consumption, handling, stability, ride comfort and NVH (noise, vibration, harshness) performances of holistic vehicle, a full-vehicle model including mechanics, electronics, vehicle dynamics and control was made using Dymola. Moreover, a model of a new drive train system such as torque vectoring differential gear was developed and connected into the full-vehicle model. Figure 3 shows an example of the full-vehicle model. Details of the model will be explained later.

Figure 3: An example of full-vehicle model

Power consumption of each system was calculated simultaneously and was used for the investigation of good balance of energy consumption and vehicle performances. At first, total power of resistances acting on the vehicle was calculated by following equations [2].

Total resistance power:

$$P_v = P_{rr} + P_{ar} + P_{sy} + P_{sx} \quad (1)$$

Rolling resistance power:

$$P_{rr} = \mu_r mg \times V \quad (2)$$

Aerodynamic resistance power:

$$P_{ar} = \rho AC_D V^2 / 2 \times V \quad (3)$$

Cornering resistance power:

$$P_{sy} = \left[ \left( \frac{d_f}{C_{pf}} + \frac{d_r}{C_{pr}} \right) \times mA_y^2 / g \right] \times V$$

$$\approx \left[ \left( \frac{1}{C_p} \right) \times mA_y^2 / g \right] \times V \quad (4)$$

Longitudinal resistance power:

$$P_{sx} = (mA_x + mg \sin \theta) \times V \quad (5)$$

Here

$\mu_r$ : rolling resistance coefficient (RRC),

$g$ : acceleration of gravity [ $\text{m/s}^2$ ],

$m$ : vehicle mass [ $\text{kg}$ ],

$V$ : vehicle speed [ $\text{m/s}$ ],

$\rho$ : air density [ $\text{kg/m}^3$ ],

$A$ : vehicle frontal area [ $\text{m}^2$ ],

$C_D$ : aerodynamic resistance coefficient,

$d_f$ : front weight distribution ratio,

$d_r$ : rear weight distribution ratio,

$C_{pf}$ : front normalized cornering power [ $1/\text{rad}$ ],

$C_{pr}$ : rear normalized cornering power [ $1/\text{rad}$ ],

$C_p$ : average normalized cornering power [ $1/\text{rad}$ ],

$A_y$ : lateral acceleration [ $\text{m/s}^2$ ],

$A_x$ : longitudinal acceleration [ $\text{m/s}^2$ ],

$\theta$ : road inclination [ $\text{rad}$ ].

Figure 4: Comparison of resistance powers while driving straight and cornering ( $V = 30[\text{km/h}]$ ) by simulation

Figure 5: Simulation results of parameter study for stability against side wind between conventional vehicle and the new small vehicle

Figure 4 shows an example of a comparison of resistance powers between straight driving and cornering. It became clear that rolling resistance and cornering resistance were rather big and reducing those resistances was essential to reduce the power consumption. From equations (2), (4) and (5), it is understood that decreasing vehicle mass and tire RRC and also increasing tire cornering power (CP, normalized by tire contact load) are effective to reduce the total resistance power and improve the energy consumption of the vehicle. However, in general, decreasing RRC tends to result in decrease of CP for ordinary tires. Moreover, it is expected that decreasing vehicle mass

will result in reduced vehicle stability against external disturbances such as side wind. Figure 5 shows a result of parameter study for evaluating stability against side wind by Dymola. Evaluation criteria ( $Y_{45}[\text{m}]$ ) in Figure 5 is the lateral deviation while driving at 120 km/h and pass a zone of 45m length with the side wind of 20m/s. In Figure 5, comparison between conventional vehicle ( $m = 1050[\text{kg}]$ ) and the new small vehicle ( $m = 600[\text{kg}]$ ) are shown. Also for the new small vehicle, some levels of normalized CP were researched. It became clear that the light-weight small vehicle is affected more than the conventional vehicle by side wind, and sensitivity of normalized CP value against the disturbance is very small. From above investigations it is indicated that developing new tire which can realize both low RRC and high CP value is necessary for reducing energy consumption. Also for coping with improving vehicle stability against external disturbances for such small vehicles, additional control of vehicle dynamics such as direct yaw moment control is considered to be necessary.

### 3 Development of necessary items to improve holistic performance of the new small vehicle

#### 3.1 New suspension system using tires with low RRC and high CP value

As mentioned in the previous section, the development of new tires for which both low RRC and high CP value can be realized will be necessary for reducing overall energy consumption. For this purpose, a new concept of tires called Large and Narrow (L&N) Concept was developed by Bridgestone [3]. It has characteristics of larger overall diameter, narrower section width and higher inflation air pressure than conventional tires. Figure 6 (cited from [3]) shows comparison of RRC and CP measurement data between ordinary reference tire, L&N tire and L&W (Large and Wide) tire representing current high performance tire. It can be seen that L&N tire has good balance of lower RRC and higher CP at high inflation pressure of 320 kPa. Thus, it was decided to adopt L&N tires for our new vehicle. Figure 7 shows a comparison of overall cornering resistance force ( $Cr$ ) calculated by the equation (6) when running on a constant radius corner at lateral acceleration of 0.4G.

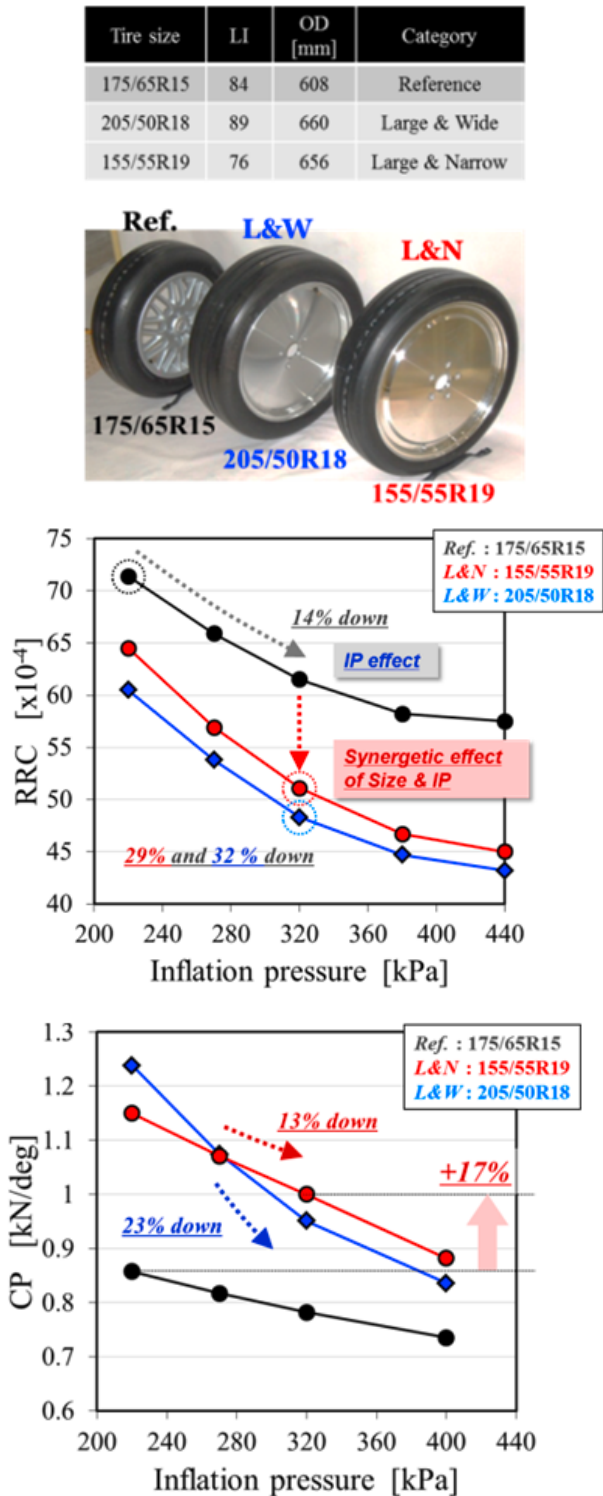

Figure 6: Measurement data of RRC and CP at Load=3.5kN [3]

Figure 7: Comparison of cornering resistance force by simulation

$$Cr = mA_y^2 g / C_p \text{ [N]} \quad (6)$$

Comparison is done between conventional vehicle and new small vehicle with ordinary tire, low RRC (but low CP) tire and L&N tire. The effect of low weight and L&N tire to reduce the cornering resistance and thus energy consumption was proved by the simulation.

However, there still are remaining problems for applying L&N tires for the new vehicle. Because of larger overall size, it has larger rotating inertia resulting in larger drive-train vibration and less controllability of driving torque than conventional vehicle. Also higher inflation pressure results in higher vertical stiffness and it is suggested to affect ride comfort and NVH (Noise, Vibration and Harshness). Thus, new suspension design is supposed to be necessary. To cope with those problems are future works.

### 3.2 Active yaw moment control by torque vectoring system

As mentioned above, it became clear that active yaw moment control to cope with external disturbances was indispensable for small light-weight vehicles. To research the best solution of this function, benchmarking of existing torque vectoring systems were performed using simulation by Dymola at first. Considering the space for mounting and also controllability, TUM:MUTE type system[4] was investigated further. In this system, a main motor connected to outer ring gear of the differential planetary gear set controls total driving torque. On the other hand, a control motor connected with an input shaft of control gear sets controls torque distribution of left and right

wheel. The function of torque distribution was confirmed by Dymola simulation as shown in Figure 8. It became clear that torque distribution ratio can be changed from 50:50 to both of 0:100 and 100:0 and more by increasing the input torque of the control motor. By this simulation, also energy consumption of both main motor and control motor was able to calculate as well as mechanical transient motion. Finally an example of desired yaw rate feedback control for the torque distribution ratio was tested. Main motor torque ( $T_m$ ) was decided by PI feedback control of difference between desired value and actual value of the vehicle speed by following equation.

$$T_m = K_{pV} \cdot (V_{ref} - V) + K_{iV} \cdot \int (V_{ref} - V) dt \quad (7)$$

where

$K_{pV}$ : Proportional feedback gain

$K_{iV}$ : Integral feedback gain

$V_{ref}$ : Desired vehicle speed

$V$ : Actual vehicle speed

On the other, control motor torque ( $T_c$ ) was calculated by PI feedback control of difference between desired yaw rate and actual yaw rate as following equation.

$$T_c = K_{pr} \cdot (r_{ref} - r) + K_{ir} \cdot \int (r_{ref} - r) dt \quad (8)$$

Figure 8: Simulation result of torque distribution ratio VS control motor power for torque vectoring differential gear system of MUTE type

where

$K_{pr}$ : Proportional feedback gain

$K_{ir}$ : Integral feedback gain

$r_{ref}$ : Desired yaw rate

$r$ : Actual yaw rate

and the desired yaw rate was calculated as below.

$$r_{ref} = \frac{K_s}{1 + sT_s} \delta_s \quad (9)$$

$$K_s = \frac{(a_f + a_r)c_f c_r V}{a_r c_r m V^2 + a_f (a_f + a_r)c_f c_r} \quad (10)$$

$$T_s = \frac{m a_f V}{(a_f + a_r)c_f} \quad (11)$$

Here,

$\delta_s$ : Steering input angle at front tire

$a_f$ : Longitudinal distance between front wheel and CG (Centre of gravity)

$a_r$ : Longitudinal distance between rear wheel and CG

$c_f$ : Cornering stiffness of front two tyres

$c_r$ : Cornering stiffness of rear two tyres.

Figure 9 shows a simulation result of the side wind test. Lateral deviation against the side wind (Y45) and energy consumption of main motor and control motor were calculated for the cases of no control, only P feedback control and PI feedback control. The contradiction between vehicle stability and energy consumption of the control motor was confirmed. Finally, development of a new torque vectoring differential gear based on parallel planetary gear sets was decided. Numerical consideration as above will enable us to design the best solution for the practical design of the systems both in mechanical aspect and electrical aspect.

Figure 9: Simulation results of side wind test between No control, P feedback control and PI feedback control of torque vectoring differential gear

### 3.3 Electric regeneration system of braking force

Figure 10: An example of calculation of each resistance power when driving on a winding circuit road

Figure 11: Comparison of driving and braking energy for some examples of driving modes

Utilizing electric regeneration of braking force by motor is effective to improve the energy consumption. In the planning phase of a new vehicle, it is necessary to decide proper size of battery capacity for the regeneration. For this purpose, realistic simulation of actual driving scenes is necessary. IPG CarMaker was used to calculate the vehicle speed, longitudinal and lateral acceleration, road decline and corner radius for actual roads. Using above data, necessary driving power and overall resistance power by the equation

(1) were calculated. Figure 10 shows an example of resistance power of each resistance force while driving on a winding circuit road. Using these results, overall driving energy and braking energy for some examples of driving mode were calculated as shown in Figure 11. Here, JC08 and US06 are regulation of driving modes for measuring fuel consumption in Japan and USA respectively. Figure 12 shows distribution of vehicle speed and longitudinal acceleration for both modes. As seen in Figure 12, US06 mode uses higher vehicle speed and acceleration than JC08 mode and results in more driving power and braking power appearing in Figure 11. Also in Figure 11, comparison of two driving styles for a winding circuit road is shown. It is observed that the defensive driving style needs less power than the normal driving style. It is assumed that braking power less than 15kW can be recuperated by the regeneration of motor in this example. It was understood that there is remained braking power which can be recuperated if the regeneration ability of battery system is large enough in the case of circuit road driving. In this example of Figure 11, these braking powers are consumed by the mechanical breaks and wasted. Figure 13 shows a result of simulation to calculate possible electricity consumption value in the cases of using battery systems whose regeneration ability are 15kW, 40kW and 70kW respectively. It became possible to estimate how large battery capacity was necessary to improve the energy consumption in each driving cases.

Consequently it was proved that these simulations were very useful to decide the proper specifications of a new vehicle in the planning phase.

## 4 Conclusions

For the investigation of overall vehicle specifications and system structures, a holistic vehicle model including mechanics, electrics, electronics, vehicle dynamics and control was made and utilized. It was proved that such a holistic model was very useful to investigate the proper specifications and system constructions in the phase of early stage of vehicle development. Modelica was very suited to make such a multi-discipline and multi-domain investigation by model-based development.

## Abstract

This paper focuses on modeling of the electric axle drive system (eAxle) used for improving vehicle stability and handling performance by means of a torque vectoring (TV) feature as well as improving vehicle traction and reducing CO<sub>2</sub> emissions by means of an electric traction feature. The function, construction and benefits of the eAxle will be explained within these contexts. An overview of the modeling of the eAxle in Dymola® will be shown. Several simulation cases are conducted to verify the effectiveness of the system for reducing fuel consumption and improving longitudinal and lateral dynamics. A co-simulation was developed between Dymola® and Abaqus® to simulate the power loss and ascertain the temperature behavior on the housing of the eAxle. Finally, the eAxle with a vehicle model was driven over a special realistic handling course using an open source software called Blender®. The dynamic behavior of the whole vehicle model (with eAxle) will be validated by means of an optical measurement process or what so called (Object Tracking).

*Keywords: Electric axle drive system (eAxle); torque vectoring (TV); CO<sub>2</sub> emission reduction.*

## 1 Introduction

Nowadays, electric and hybrid vehicles are becoming increasingly important for many reasons, such as increasing oil prices and environmental pollution. Other contributory factors are legislation like, CO<sub>2</sub> emission reduction, taxes and zero emission zones. Nonetheless, e-mobility vehicles are much more efficient than conventional vehicles because they can regenerate, store and reuse kinetic energy.

The Schaeffler Group develops three types of eAxle: A high-voltage (HV) eAxle, which is very

suitable for electric and full-hybrid vehicles. This model has two electric motors (traction and TV). The second type is a 48-volt (48V) eAxle, which is optimally suited for mild- hybrid vehicles. It also has electric traction and TV motors. The third type is an (48V+TV) eAxle, which has just one 48V electric motor that is used in traction mode until a predefined speed limit and it then uses as a TV motor. This type has 3 planetary gear stages, two for traction mode and the third for TV mode. The last type of eAxle is a huge step forward in the development of the eAxle. A HV eAxle [Figure 1] is presented in this paper.

The HV eAxle has a traction motor with a maximum power and torque of 65 kW and 160 Nm respectively. With two planetary gear stages, the traction motor can drive the vehicle in full electric mode or assist the internal combustion engine (ICE).

Figure 1: HV electric axle drive system

The TV motor has a maximum power of 6 kW, which is transmitted via a planetary transmission to supply up to 1100 Nm of delta torque between the left and right wheels.

The dynamics and agility of the vehicle can be significantly improved with the TV function. The steering characteristics are very responsive because

there is less vibration and the driver has an improved feel of the road conditions through steering feedback. Traction is improved especially with regard to critical road conditions like  $\mu$ -split. The most important benefit of the TV function is the improvement to the stability and safety without any adverse effects on the longitudinal dynamics and traction. This means no power losses or velocity decrease in comparison with other stability technologies that use a brake-split on different wheels.

An advantage of eAxle is the high potential for reducing fuel consumption and emissions because it is driven by electrical energy.

## 2 Modeling of the eAxle

The Schaeffler eAxle is a mechatronic system that contains mechanical parts (such as the transmission), electrical parts (electric motors) and thermal and control systems. It therefore requires a modeling approach that allows modeling of multi-domain systems. The modeling language Modelica® offers this facility and at the same time allows the model to be used on different simulation platforms. Therefore, the following model of the Schaeffler eAxle has been modeled using Modelica (www.modelica.org) in Dymola® which is a Modelica-platform tool.

### 2.1 Transmission model

The mechanics of the transmission [Figure 2] have been modeled with the 1D mechanics of the Modelica Standard Library (MSL). As an interface to the entire vehicle model, the transmission model has connectors for the torque vectoring motor, traction connector (which can be connected to the traction motor or ICE depending on the type of eAxle) and two output connectors (which are connected to the shafts of the left and right wheels). A deeper model level divides the model into the components "planetary gear sets", "differential" and "overlay gear set". The torsional rigidity of these components is determined by FEM analysis and mapped as linear springs in the model. The mass inertia is derived for all components from the CAD data and implemented as a rotating mass in the model.

The power losses in the traction path are implemented by means of a simulated map that has

been calculated using the WTplus® program. This map is just a 3D matrix that depends on the torque, angular velocity and temperature (which will be calculated in Abaqus and imported back into Dymola by co-simulation).

The traction gear ratios are 12.34 for first gear and 4.22 for second gear. The TV gear ratio is -37.72.

### 2.2 eAxle model

The transmission model is then integrated with the traction, TV motors and gearing signal into the eAxle model. The eAxle model has 3 input signals (throttle of the traction motor, which comes from the driver; throttle of the TV motor, which is regulated by the TV controller; and the required gear, which depends on the hybrid strategy).

Figure 2: Transmission model

The efficiency-map and torque-over-angular velocity map of both motors (traction and TV) have been measured. The models of these motors have been implemented based on these maps (not a physical model)

The losses of the motors and transmission have been totalized to enable calculation of the actual temperature of the transmission and the temperature behavior on the eAxle housing by means of co-simulation with Abaqus.

The derating function of the electric motors has been defined by the motor supplier depending on thermal measurements of the motors. Thus, the derating function supplies a time-interval (for example, the traction motor is allowed to run with the maximum possible power for up to 5 seconds (overload time) and then has to run with less than or equal

the nominal power for at least 20 seconds (relief-time)). This function has been implemented with help of StateGraph library of MSL as shown in [Figure 3].

Figure 3: Derating model

### 2.3 TV controller

The TV controller is the unit responsible for defining the required torque of the TV motor in order to produce the necessary and effective yaw torque for the vehicle. [Figure 4] shows a diagram of the TV controller.

The TV controller calculates the desired yaw rate depending on the steering angle and some vehicle conditions as follows.

$$\dot{\psi}_d = f(\delta, v_x, a_y, \beta)$$

where,  $\dot{\psi}_d$  is the required yaw rate,  $\delta$  is the steering angle at the wheel,  $v_x$  is the longitudinal velocity,  $a_y$  is the lateral acceleration and  $\beta$  is the side slip angle.

The required yaw torque is calculated by comparing the required and the actual yaw rate.

$$T_{yaw\_d} = f(\dot{\psi}_d, \dot{\psi}_{actual})$$

Finally, the required vectoring torques that should be supplied by the TV motors are calculated in the following equations.

$$T_{V_{FA}} = \alpha \cdot \frac{b \cdot R}{-2 \cdot n_F} \cdot T_{yaw\_d}$$

$$T_{V_{RA}} = (1 - \alpha) \cdot \frac{b \cdot R}{-2 \cdot n_R} \cdot T_{yaw\_d}$$

where,  $T_{V_{FA}}, T_{V_{RA}}$ : Torque of TV motor of front/rear axle respectively,  $\alpha$ : Fraction ratio of TV between front/rear axle (if  $\alpha = 0$  only rear axle TV is active, if  $\alpha = 1$  only front axle TV is active, otherwise the TV of both axles is active with that fraction ratio),  $b$  is the vehicle track base,  $R$  is the wheel radius and  $n_F, n_R$  are the TV gear ratio of the front/rear axle respectively.

Figure 4: Diagram of TV controller

### 2.4 Vehicle model

The HV eAxe model was inserted into a drive train model and integrated together with a vehicle, driver and road models from the Vehicle Dynamics Library developed by Modelon®.

For the consumption analysis, the eAxe model was integrated with the rest of the vehicle model, driver and street models of the Power Train library developed by the DLR Institute of System Dynamics and Control.

### 2.5 Co-simulation between Dymola and Abaqus

A detailed thermal model of the eAxe has been modeled in Abaqus in order to carry out an adequate thermal analysis of the power losses in the eAxe due to the traction motor, TV motor and transmission. A co-simulation between Dymola and Abaqus is then used.

The Abaqus co-simulation technique can be used to solve complex systems that include electron-

ics such as control systems, electro-mechanics, hydraulics, heat transfer and pneumatics by coupling Abaqus with Dymola, a general-purpose logical modeling software distributed by Dassault Systems. Structural responses computed by Abaqus/Standard or Abaqus/Explicit are coupled at run time with solutions provided by Dymola [6].

The Abaqus modeling method called “physical modeling” is the complementary modeling method to “logical modeling”. Physical modeling is An FEM application, which uses a precise knowledge of the geometry to mimic the real world at a fine-grain level.

The Abaqus-Dymola coupled simulation capability targets simulations involving compliant response of a component or subassembly embedded in a larger, more complex system. All Abaqus features, including nonlinear materials, nonlinear geometric effects, and contact are available for use. In fact, any time-domain Abaqus model can be used as an Abaqus-Dymola co-simulation model with very few simple modifications[6].

The power losses of the eAxle in the Dymola model are defined with the same name as the actuators in the Abaqus model (Actuators are sources used to actuate the physical model). A virtual sensor is defined in the Abaqus model to measure the temperatures at some points and send them to Dymola. This sensor should have the same name as the input signal in the Dymola model. The Dymola model is then translated and the dymosim.dll file is selected by the plug-ins option in Abaqus.

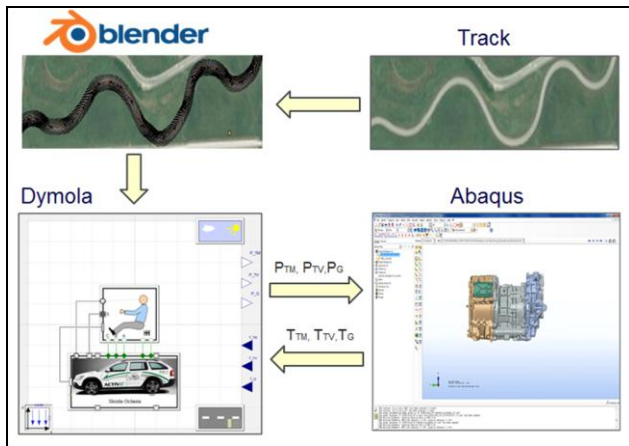

Figure 5: Co-simulation between Dymola and Abaqus, with a special realistic road.

In order to ensure a high level of actuation in the traction and TV motors, a special handling course road is used. The handling course road is imported as an image into Blender® in order to preprocess and generate the Modelica road file for implementation in the Dymola model [Figure 5]. The vehicle model is then simulated on the handling course road and the power losses of the eAxle are sent to Abaqus at every simulation step. Abaqus calculates the temperature values and sends them back to Dymola to run the next simulation step. These temperature values are necessary to calculate the power losses of the transmission.

### 3 Simulation Results

The consumption analysis and dynamic simulation of the vehicle have been calculated according to the vehicle data in Table 1.

Some comparisons have been made between the conventional vehicle model (without an eAxle) and the hybrid vehicle model (with an eAxle). The hybrid vehicle model is 80 kg heavier than the conventional vehicle model (weight of eAxle) for all following simulation cases.

Table 1: Vehicle specifications

Vehicle mass		2105 kg
Dynamic tire radius		0.3186 m
Frontal area		2.42 m <sup>2</sup>
Friction coefficient of road		0.9
Moments of inertia of the vehicle		I <sub>xx</sub> =709 I <sub>yy</sub> =3281 I <sub>zz</sub> =3358 kg.m <sup>2</sup>
Distance CG to the front, rear axle		1.269, 1.308 m
Vehicle track base		1.532 m
Mass of eAxle		80 kg
Traction motor	P <sub>max</sub>	65 kW
	T <sub>max</sub> , T <sub>nom</sub>	160, 140 Nm
	Speed max	14000 rpm
TV motor	P <sub>max</sub>	6 kW
	T <sub>max</sub>	30 Nm
	Speed max	14000 rpm
Battery	Energy	10 kWh
	V <sub>max</sub> , V <sub>min</sub>	365, 267 Volt
	SOC <sub>max</sub> , SOC <sub>min</sub>	0.8, 0.2

#### 3.1 Fuel consumption analysis

To determine the save fuel by using the eAxle model, the vehicle model is driven in the New European Driving Cycle (NEDC) for 100 km with four different cases: Conventional, hybrid with a ful-

ly charged battery, hybrid with a half charged battery and hybrid with a flat battery. The last case has been considered to specify the fuel saved in the case when the eAxle is used with no power in the battery, which means the eAxle can be driven only with the energy recuperated by braking. [Figure 6] shows the vehicle driving in two sequentially cycles of the NEDC. The eAxle firstly starts to recuperate the kinetic energy by braking and using it after that to drive the vehicle using electric power only for some period of time.

Figure 6: Hybrid vehicle driving in the NEDC with flat battery at beginning.

Although the eAxle makes the vehicle 80kg heavier, it allows a reduction in fuel consumption of at least 18% compared with a conventional drive. If the battery is pre-charged, the eAxle enables a reduction in fuel consumption of up to 38% depending on the state of charge of the battery.

The fuel consumption over time and the percentage of fuel saved by the hybrid vehicle in comparison with a conventional vehicle when driving up to 100 km are shown in [Figure 7].

Figure 7: Fuel consumption in liters over time and percentage of overall fuel saving in a hybrid and conventional drive.

## 3.2 Dynamic analysis

### 3.2.1 Longitudinal dynamic

The eAxle almost makes a normal car into a sports car by using the 65kW traction motor to assist the ICE.

Simulation results show that the vehicle model without an eAxle takes about 6.6 seconds to accelerate from 0 to 100 km/h, while the hybrid vehicle took about 5.1 seconds, which means the eAxle can improve the longitudinal acceleration of the vehicle by 29% on average as shown in [Figure 8].

Figure 8: Acceleration from 0 to 100 km/h for both a conventional and a hybrid vehicle. i) Vehicle velocities. ii) Longitudinal acceleration up to the 1<sup>st</sup> second.

The eAxle can quickly supply a high traction torque even at low angular velocities, which gives the vehicle instantaneous high longitudinal acceleration. This fast response also gives the ICE a chance to supply a high torque in a shorter time because the eAxle drives the vehicle to a relatively high velocity which means the ICE runs with sufficient angular velocity to supply a high torque (ICE supplies low torques at low angular velocities). This explains the dramatic increase in longitudinal acceleration of the hybrid vehicle up to the 1<sup>st</sup> second in comparison with a conventional vehicle, as shown in [Figure 8].

### 3.2.2 Lateral dynamics

The TV feature has a big influence on the lateral dynamics performance because the TV motor with a maximum torque of 30 Nm can be used in conjunction with the TV gear to provide the vehicle

with a torque difference of up to 1100 Nm between the right and left wheels.

The vehicle is more stable and safer when it is driven in curves and can also be driven with a higher velocity. The driver will also notice the softer ride and ease of driving using the TV (driving pleasure).

Two simulation cases show the advantages of TV for the lateral dynamics, steering step response and cornering performance.

### 3.2.2.1 Steering step response

To verify the advantages of TV on the steering, the driver steers to 60 degree with 400 degree/sec while driving at 90 km/h. [Figure 9] shows the steering angle, while part b shows the yaw rate of the vehicle with and without TV. It is so clear that the yaw rate of the vehicle has a smaller overshoot when using the TV because it increases the torque on the outer wheel and decreases torque on the inner wheel. The yaw rate also has less fluctuation and reaches a steady state faster because the TV compensates the fluctuation by biasing the difference in torque between the wheels.

Figure 9: Step response test of a vehicle driven at 90 km/h. i) Steering angle. ii) Yaw rate with and without TV.

### 3.2.2.2 Cornering performance

A circular road with a 40 m radius curvature has been used to simulate the vehicle model with and without the TV function. The vehicle is driven at 65 km/h.

The simulation results [Figure 10] show that:

- TV decreases the gradient of the steering angle ( $\delta$ ) over the lateral acceleration of the vehicle [region1]. This means the steady-

state behavior of the cornering performance of the vehicle is improved by using TV.

- The maximum level of lateral acceleration can be extended by using TV [region2], which gives the vehicle a wider range of stability.
- The TV decreases the necessary steering angle at high lateral acceleration, which is reflected in increased safety and driving pleasure.

Figure 10: Steering angle over lateral acceleration with a 40 m radius curvature at 65 km/h.

The vehicle takes 8.2 seconds to negotiate the curve using TV and 8.3 seconds without TV. In addition, the total energy used by the traction and TV motor to negotiate the curve with TV is 1% less than the energy required when the TV is switched off (traction motor only) as shown in [Figure 11].

A reduction in fuel consumption of approximately 1.9% could be achieved by using the ICE instead of the traction motor of the eAxle (This configuration is suitable for special designs of low-voltage eAxle). This means the TV feature not only improves the lateral dynamic performance, but also saves some fuel.

Figure 11: Energy consumption during cornering with and without TV.

### 3.3 Dymola-Abaqus co-simulation

The vehicle is driven at 60 km/h on the handling course road and Abaqus calculates the temperatures on the housing of eAxle depending on the power losses [Figure 12].

These temperatures are used to define the conditions of the electric or hybrid strategy.

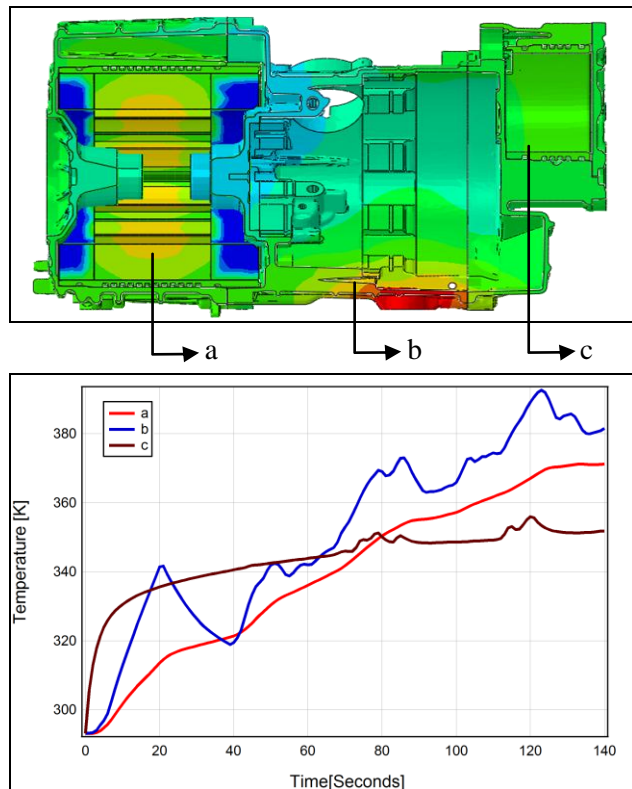

Figure 12: Temperatures on the eAxle housing a) on the traction motor. b) on the transmission and c) on the TV motor.

### 3.4 Validation of vehicle model

The entire vehicle model was validated on the basis of the lane-change test (ISO standard 3888-2) by using an optical measurement process. The measurement process analyzes the motion of optical markings [Figure 13.a] in a video recording of the driving maneuver (object tracking). With the corresponding software Blender®, the variation in vehicle position and orientation on the test track can be determined over time[3]. A comparison between roll angle of the test vehicle by the object tracking and simulation result is presented in [Figure 13.b].

○ Inertial system. ○ Vehicle

a.

b.

Figure 13: a) Test vehicle with tracking markers. b) Roll angles in simulation and object-tracking validation.

## 4 Conclusions and Outlook

The modeling of a multi-domain system in Modelica, and the concept of building an electric active drive system for reducing fuel consumption, improving traction and providing yaw stability control have been discussed.

Modelica has a major advantage for dealing with a model that has many components from different disciplines.

Simulation results, which prove the advantages of the eAxle system in terms of dynamics and consumption are presented. A co-simulation has been developed between Dymola and Abaqus to investigate the thermal effects on the eAxle.

A realistic road has been constructed and preprocessed with other animation tools and can be easily and flexibly exported to Dymola.

Another simulation case has been started to investigate the effect of recuperation and the extra weight of the eAxle on the fuel consumption by considering the influence of elevation when the vehicle is driven on a road with a gradient. Unfortunately, the model of the driver in the PowerTrain library is unable to maintain the vehicle's velocity close to the

requirement when the vehicle is driven downhill, which leads to non comparable consumption results.

Vehicle object tracking for validation the vehicle performance has been presented. A validated case between simulation result and reconstructed data from object tracking has been compared and shown.

## Abstract

The paper introduces a new concept of modeling the overall control unit of hybrid electric vehicles in *Modelica*. The work focuses on a structure which can simulate substantially different vehicle concepts without changing the structure of the control unit. Based on this universal implementation different scenarios can be simulated rapidly and consequently cheaply, including fundamentally different drive trains ranging from conventional to purely electrical including hybrid versions.

*Keywords:* object-oriented control unit modeling; control unit template modeling; object-oriented electrified vehicle modeling

## 1 Introduction

Ever increasing demands on fuel efficiency are requested from both politicians and customers. This should happen without increasing the costs and without compromising on performance of the vehicle [2]. Therefore, simulation in the concept stage of a vehicle development is getting more and more important, because with the aid of simulation design decisions can be supported in a more efficient overall process that is consequently resulting in cost savings [4]. This is especially true when designing complex systems which are state-of-the-art in the form of hybrid electric vehicles (HEV).

Nowadays, several different HEV topologies are state-of-the-art, for example series hybrid, parallel hybrid or power split hybrid. Furthermore, from every topology multiple modification levels are available. Until now, if a rough layout of a HEV has to be simulated, a very specific CU (control unit), specially adapted to each different vehicle topology has been modeled. This process is error-prone, time consuming and in turn associated with high costs. Due

to these facts the manufacturers postulate the development of a universal CU for simulations.

Implementations of individual HEV topologies have been discussed many times in literature, but the implementation of a standardized template for a universal CU has not yet been provided.

Examples are given in [8] and in [9], where fuel consumption simulations - on basis of two commercial *Modelica* libraries: the *PowerTrain* library [5], [7] and the *SmartElectricDrives* library [1] - of different HEVs are discussed.

Another example of a library for simulation of HEVs is given in [3]. The used library is called *eVehicleLib* and can be used for fuel and energy consumption simulations as well as other purposes.

Both, the *PowerTrain*- and the *eVehicleLib* library contain models for process control, i.e. for the operating strategy but no template of a universal CU for different vehicle topologies. The concept presented in the paper fulfills this request of the manufacturers.

The paper focuses on HEV structures, what is reasonable as purely electric or conventional drive trains may be treated as a simplification of suitable hybrid versions. An example will be demonstrated in Section 5 where the hybrid car (BMW i8) is simulated as a conventional vehicle by just changing controller parameters.

## 2 Hybrid Electric Vehicles

Basically, HEVs can be classified on either the type of the power train or by their degree of hybridization. Speaking of type of power train, one can distinguish between series-, parallel- and power-split hybrids. The classification by degree of hybridization contains micro, mild and full hybrid.

Due to the fact that a HEV, in contrast with a conventional vehicle, has two energy converting systems -

usually a combustion engine (CE) and an electric machine (EM) - more degrees of freedom in generating traction energy are available. Which possibilities are available depends on the arrangement of the CE and the EM in the drive line, i.e. on the HEV topology [2].

### 3 Modeling Approach

To design a template of a universal CU, which can be used to simulate different kinds of HEVs, it must first be understood how the CU interacts with the remainder of the entire vehicle system. Therefore, a decomposition of an entire vehicle system into basic objects is necessary. The first division is done into four main parts: a drive environment, an environment, a vehicle itself and the control unit.

The drive environment emulates the human driver, i.e. it influences the vehicle in longitudinal direction with the accelerator and brake pedal (lateral direction is neglected). The schematic function of the drive environment is illustrated in Figure 1. Depending on a reference velocity (supplied by the driving cycle) and an actual velocity (supplied by the vehicle) the accelerator- and brake pedal position is computed by the driver. These signals are sent to the CU which computes signals for the vehicle. Therefore, a direct interaction between the CU and the drive environment is given.

Figure 1: Schematic structure of the drive environment

In the vehicle it is distinguished between objects which are required for generating traction energy and the ones which are not, i.e. the vehicle is grouped into a drive line and auxiliary units, see in Figure 2. The CU provides on the one hand signals for the drive line, e.g. torque requirements for the CE and the EMs and on the other hand for the auxiliary units, e.g. the available power for the auxiliary units. Furthermore, sensor signals from the drive line are necessary in the CU, e.g. the actual vehicle speed. Therefore, the CU has a direct interaction between the objects from the vehicle.

The environment includes all effects from outside of the entire vehicle system and provides it to the ve-

Figure 2: Schematic structure of the Vehicle

hicle, see Figure 3. The CU requires signals from the environment which as well influence the vehicle and therefore, an indirect interaction between the CU and the environment exists.

Figure 3: Schematic structure of the environment

Figure 4 shows the decomposition of the entire system in summarized form, whereas the interaction between the objects is indicated by arrows.

Figure 4: Schematic structure of an entire system

The interaction between the CU and the rest of the entire vehicle system is clearly defined. Now, the decomposition of the CU has to be carried out in a way that it can be reused for different HEV topologies. To make the structure flexible enough a controller with two levels is introduced (see Figure 5). In the primary layer the HCU (hybrid control unit) determines the current driving mode. Depending on the output of the primary layer the second level of hierarchy computes the desired signal for the corresponding drive line component (see Figure 5).

- BCU (brake control unit)
- ESCU (electric storage control unit)
- CCU (clutch control unit)
- GBCU (gearbox control unit)

- ECU (engine control unit)
- EDCU (electric drive control unit)

Figure 5: Schematic structure of the CU

To test the controller three parts are necessary, of which the first is to design a template for the overall system, which is shown in Figure 6. For this purpose a library with basic components was created to replace the corresponding parts of the template. As the focus of this paper is to present the structure of the controller the models for testing (*Drive Environment*, *Vehicle* and *Environment* in Figure 6) are not discussed here in more detail. Moreover a considerable amount of attention was paid to the fact that well defined interfaces of each model were used in the template and therefore every component model can be adapted or changed easily, thanks to Modelica's object-orientation. In the following section we will focus on the implementation of the universal control structure that is shown in the *Control Blocks* part of Figure 6.

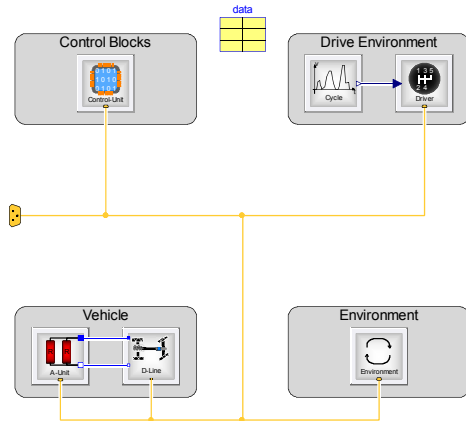

Figure 6: Template of the entire system

## 4 Universal Control Unit Modeling

Manufacturers tend to protect the control strategy as trade-secret because it represents one of their core knowledge. Therefore, the implementation of each part of the CU must be created in a way that it can easily be adapted and/or replaced. The structure of the

implementation of the CU is based on Figure 5 and its implementation is shown in Figure 7.

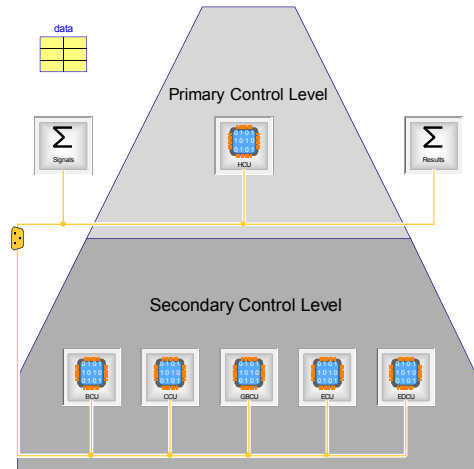

Figure 7: Template of the universal CU

### 4.1 Bus Structure

Looking at Figure 7 one can easily see, that the implementation is heavily relying on a bus structure. It was applied to the massive amount of control signals within the controller that have to be dealt with. Moreover it enhances the flexibility and maintainability of the overall controller. To reduce errors within connecting signals from the bus and as well enhancing maintainability connectors are introduced that only feed values from the bus to a signal connector of suitable type (Real, Integer, Boolean). Although those adapter models are very simple they are valuable in certain cases. When e.g. a variable on the bus is renamed only the connector has to be modified in contrast to every single connection relying on that variable.

In the current implementation the bus has a flat structure without any grouping of variables. After it turned out that the bus has close to 100 variables it would be well worth the effort to restructure the bus with a hierarchy related to e.g. Figure 4.

### 4.2 Primary Control Level

The primary control level solely consists of the HCU as shown in Figure 7. It is the centerpiece of the CU as it supervises all the other control units of the secondary control level. To implement a universal HCU it is necessary to consider all possible driving modes of all HEV topologies. These are

1. Standstill with CE off (StandStill)

2. Standstill with CE on (StandStillEngine)
3. Electric Driving (ElectricDriving)
4. Friction braking (Braking)
5. Regenerative braking (RegenerativeBraking)
6. Boosting (Boosting)
7. Shifting of the Operation Point (Shifting-OperationPoint)
8. Conventional Driving (ConventionalDriving)

whereas the names in the brackets denote the variable names used in the model itself.

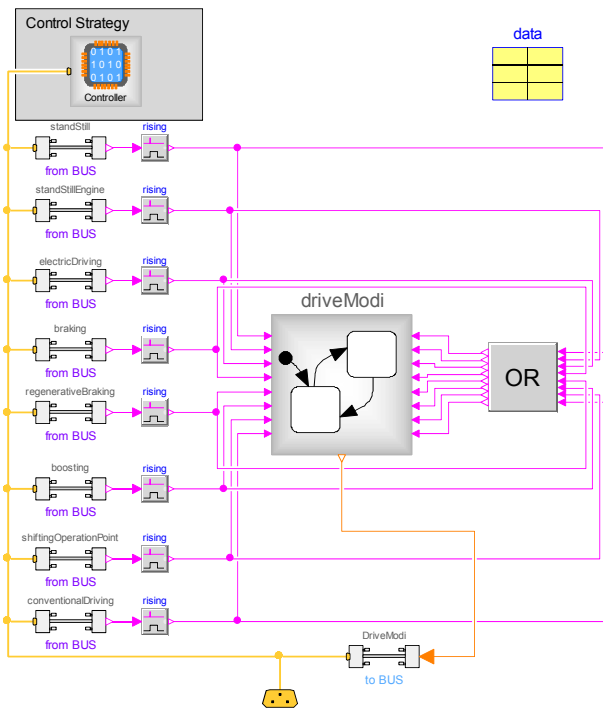

Figure 8: Implementation of the HCU

The HCU (Figure 8) has to decide which of those driving modes is active e.g. depending on driver inputs or internal states of the vehicle. The first prerequisite to be able to take that decision is to know which of those driving modes are available in the current vehicle configuration. Therefore parameters to activate driving modes independently of each other are provided in the data record shown in Figure 8.

In the current implementation independent models are used to decide which driving mode is active as shown in Figure 9. All of them have Boolean outputs each one representing a possible driving mode. This implementation guarantees maximum flexibility but is not the most straight-forward implementation.

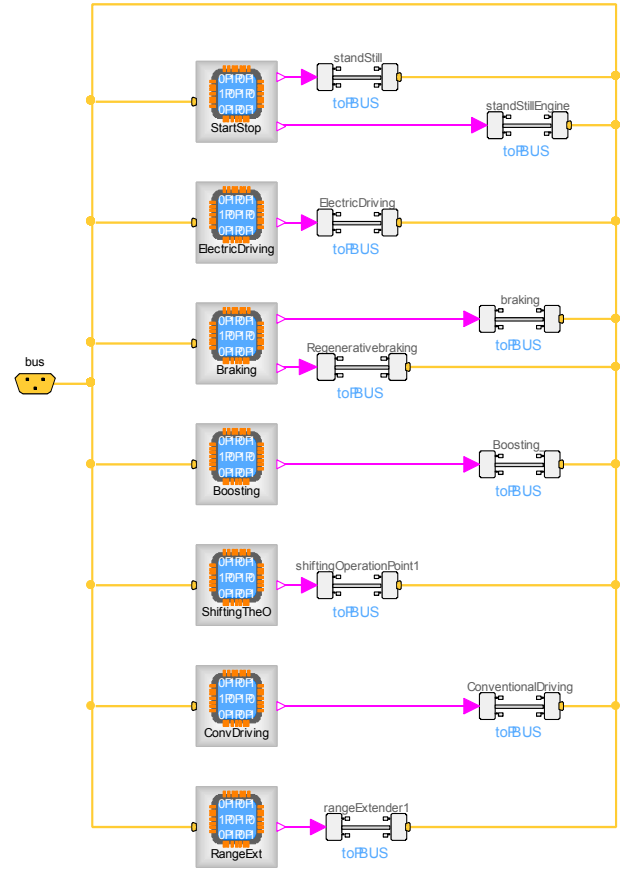

Figure 9: Implementation of the Control Strategy within the HCU

To have distinct behavior it has to be ensured that in each time step only one driving mode is active within the HCU. To ensure that, the modeling is done via the *state graph 2* library<sup>1</sup>. The implementation shown in Figure 10 is a combination of eight parallel loops, one for each driving mode. This model is used named *driveModi* in Figure 8. The loops consist of an activate and a deactivate transition and therefore of an on and an off step. The output of the HCU is an integer variable that is put to the bus indicating the current drive mode. This drive mode is then utilized by the secondary level controllers (Figure 7) to generate input signals for the drive train components. As a result of this structure it is not only possible to simulate HEVs of different structure, but also purely electric vehicles and conventional vehicles. Therefore, the modeler can simply choose a hybrid vehicle topology and based on that the possible and desired driving modes are enabled in the HCU.

The range extender operation is an exception to that rule. This mode can be interpreted using a source of power for the battery without any power directly

<sup>1</sup>For further information it is referred to [6]

transferred to the power train. Alternatively it could be seen as part of the auxiliary units as it does not generate traction force. It can therefore not be integrated in the integer variable that represents the driving mode, as some other driving mode has to be active to compute the control signals for the components of the drive train. Then the integer value for the driving mode would have to take two values. It is therefore represented by an additional Boolean variable on the bus.

Figure 10: Driving mode selection via state graphs

Consequently the driving modes are represented by an integer variable (driving mode 1 - 8), which is computed via the state graphs and a Boolean variable (driving mode 9), which is computed in the Controller block.

## Modifications

The driving modes are simple to adapt or to replace as only the Boolean output has to be fed with a meaningful value. If an additional driving mode should be implemented a new driving mode controller in the *Controller* block and an additional loop in the *DriveModes* block has to be implemented.

## 4.3 Secondary Control Level

In the following sections the second layer controllers are shown starting with the engine control unit that is discussed in a bit more detail whereas the others shall be described only briefly.

### 4.3.1 Engine Control Unit

The ECU is responsible to calculate the normalized torque request of the CE. Furthermore, the signals for the starter generator and the signals to bring the CE into idle mode or switch it off are computed in this controller. The main areas of functionality are shown on the left side of Figure 11. These are

- Conventional Driving
- Shifting the Operating Point and
- Boosting

represented by different paths through the model within the left three boxes in the model.

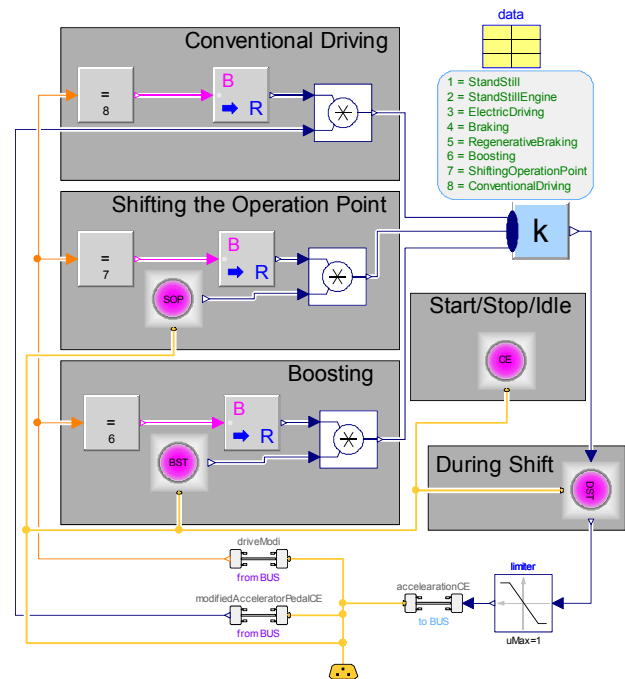

Figure 11: One possible controller of the combustion engine

They compute an output signal that represent the combustion engine's torque demand depending on the variable *driveModi* that is taken from the bus via the adapter shown in the lower part of Figure 11. The combination of compare block, Boolean to real converter and multiplication with the output basically act as an activation and deactivation of the single path. The *SOP* and *BST* blocks represent implementations of the functionality indicated by their name.

The additional blocks for *Start/Stop/Idle* and *During Shift* take responsibility that the CE acts like one would expect during the operation states indicated by their name.

Flexibility is granted by the possibility to replace the blocks for *SOP*, *BST* etc. or by replacing the overall *ECU* (Engine Control Unit) within the *CU*. Which possibility is more suitable has to be decided within the application that is targeted.

#### 4.3.2 E-Drive Control Unit

The EDCU is responsible to calculate the normalized torque requests of the EMs. Furthermore, in this controller it is ensured that the computed signals are sent to the corresponding EM (in case more than one EM is available).

The implementation of the EDCU is split into different areas, i.e. one for each driving mode where an EM is involved. By this structure it is clearly defined how the normalized torque request signal for the EM is calculated in every driving mode. Moreover, by this implementation there is a clear separation enabling simple replacement of strategies depending on driving modes.

Due to the bigger amount of driving modes that the electric drives are included compared to the combustion engine the model gets more complex than the one in Figure 11 as one can see from Figure 12.

#### 4.3.3 Gearbox Control Unit

The task of the GBCU is to evaluate the moment of shifting a gear up or down. In a real vehicle the shifting is dependent on different parameters, e.g. vehicle speed, slope of the road, actual gear level. To simplify the implementation it is assumed that the shifting is only dependent on the actual vehicle speed, i.e. the gear shift depends on predefined threshold values. The output is the actual gear level and is represented by an integer variable.

#### 4.3.4 Clutch Control Unit

The CCU is responsible for opening and closing the clutches. The implementation is similar to the EDCU and ECU. That means that the CCU is split into different areas and, therefore, it is easy to adapt, expand or replace the controller.

#### 4.3.5 Brake Control Unit

The BCU has the task to split the required brake torque into a recuperation brake and a friction brake amount. Two different regenerative braking strategies are im-

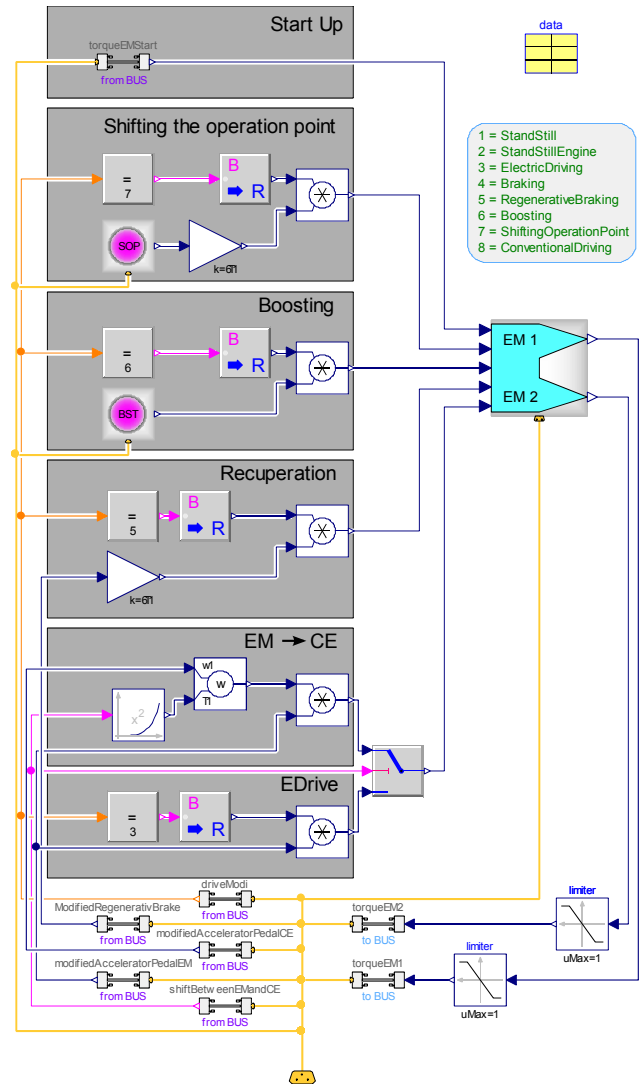

Figure 12: One possible controller of the electric machine

plemented: the series-<sup>2</sup> and the parallel<sup>3</sup> recuperation strategy.

#### 4.4 Other Models

In Figure 7 models besides the primary and secondary control level. These will be discussed in this section.

##### 4.4.1 Signals

For simulation of a conventional vehicle the accelerator pedal position can be directly used to scale the

<sup>2</sup>As long as the required deceleration is not higher than the provided generator deceleration, the generator brake is solely used. When the required deceleration increases, the friction brake is added.

<sup>3</sup>The generator and the friction brake are acting together in a fixed ratio.

maximum torque of the CE. In comparison to that, HEVs have at least two energy converting systems. Therefore the accelerator pedal position must be used to scale the maximum available torque for forward motion, which in most cases results from a combination of the torques of the CE and the EM.

In this block the conversion of the accelerator- and brake pedal position into normalized input signals is implemented.

#### 4.4.2 Results

The *Results* block is for the computation or display of values which are necessary for evaluating the simulation, for example the fuel consumption.

### 4.5 Auxiliary Units

The auxiliary units are all power units, which are not primarily needed for generating traction energy. Therefore they are not part of the HCU directly as it focuses on components for traction energy generation. Still in modern vehicles a multitude of auxiliary units can be found, e.g. an air conditioning system or a lube oil pump. The power controlling of the auxiliary units is realized via a priority list, i.e. the available electric power is shared depending on the driving mode.

Figure 13 illustrates the schematic function of the priority list. The required power from the drive line and from the auxiliary units is sent to the priority list block. This block splits the available power depending on the drive mode and sends the results to each block.

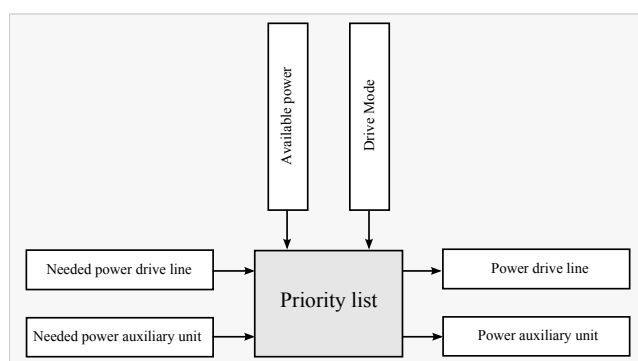

Figure 13: Schematic function of the priority list

## 5 Simulation

To demonstrate the universal applicability of the designed controller, two different vehicles are simulated. One target of simulations like these could be to judge

their fuel consumption during common drive cycles. The intention was to pick one vehicle with very high complexity, which is why the BMW i8<sup>4</sup> was chosen. Additionally the BMW i8 was operated as it is intended to and as a conventional vehicle by deactivating the hybrid operation modes. The BMW i3<sup>5</sup> was picked due to its very different structure that has to be covered with the same controller.

The driving modes in shown the simulation results in Figures 15, 16 and 18 are referring to the ones listed in Section 4.2.

It is important, that not all parameters for the models were exactly known which make the absolute results differ from real world values. Still relative comparisons based on different operating strategies are feasible and demonstrate the flexibility of the designed controller.

### 5.1 BMW i8

It is exemplarily shown how a comparison between the fuel consumption of the BMW i8, used as a conventional vehicle, and the BMW i8, used as an HEV could be made (driving cycle: NEDC).

At first a fuel consumption simulation of the BMW i8 as a conventional vehicle is run. For that solely the conventional driving mode is enabled in the HCU, i.e. only stand still with engine on, friction braking, and conventional driving are possible.

The second step is to run the fuel consumption simulation of the BMW i8 as an HEV. Therefore, the suitable driving modes are enable in the HCU, i.e. start-stop automatic, regenerative braking, electric driving, boosting, shifting of the operation point and conventional driving.

The changes between the simulations come down to selecting the boolean parameters that enable or disable the driving modes mentioned above within the parameter window. No modifications of the single controllers in any level of hierarchy is necessary.

### Result

The results of the fuel consumption simulations utilizing the NEDC are shown in Figure 14, whereby the dashed line represents the BMW i8 as a conventional vehicle and the constant line in the BMW i8 as a HEV. More important regarding this paper is how the controller behaves with respect to the driving modes that

<sup>4</sup>Is a special case of a parallel structure, called through the road hybrid or axle split hybrid.

<sup>5</sup>Is available as a purely electric vehicle or as series HEV

are activated. This is presented in Figure 15 and 16. In Figure 15 mainly the modes 1 (StandStill), 3 (Electric-Driving) and 5 (RegenerativeBraking) are active during the first 800 seconds of simulation. Afterwards the highway cycle starts, where 7 (ShiftingOperation-Point), and 8 (ConventionalDriving) are active.

If the BMW i8 is configured by a few clicks to be operated as a conventional vehicle only the modes 2, 4 and 8 are available resulting in Figure 16.

The fuel consumption of the BMW i8 as a conventional vehicle is  $0.98 \frac{1}{\text{NEDC}}$  ( $8.89 \frac{1}{100\text{km}}$ ) and as an HEV  $0.61 \frac{1}{\text{NEDC}}$  ( $5.53 \frac{1}{100\text{km}}$ ). In other words, the use of the BMW i8 as an HEV instead as a conventional vehicle effects a fuel saving of approximately 38 %.

### BMW i3

This investigation focuses on the effect of a range extender (10l tank volume) on the driving range of the BMW i3 (driving cycle: WLTP).

At first a driving range simulation with the BMW i3, used as a purely electric vehicle, is carried out. Therefore, the available driving modes are enabled in the HCU, i.e. start-stop automatic, electric driving and regenerative braking. Afterwards, the second drive range simulation is executed, with the difference that the range extender mode is additionally enabled in the HCU.

### Result

The results of the driving range simulations are illustrated in Figure 17. The upper curve is driving range of the BMW i3 as a purely electric vehicle and the lower curve the driving range of the BMW i8 with an additional range extender.

The driving range of the purely electric vehicle is 112.4 km and with the additional range extender 287.7 km. This links to a surplus of driving range of approximately 175 km.

Figure 18 shows the driving modes that are active during the simulation of a WLTP cycle for the purely electrically driven BMW i3 without range extender. It shows that only the modes 1 (StandStill), 3 (Electric-Driving) and 5 (RegenerativeBraking) are active in this case. The controller structure was the same as for the simulations carried out with the BMW i8, with necessary changes to the secondary level controllers due to other components used.

## 6 Conclusion

To summarize, the presented controller structure can be seen as a good starting basis for manufacturers for the simulation in the early design phase of a vehicle propulsion system. The presented implementation of a universal control unit provides a simple and time saving possibility to quickly simulate fundamental design changes in the system, which was the target for this development. Additionally the unification of the controller structure comes with other advantages like quicker orientation in non-familiar projects.

The presented implementation is in a prototype stadium and there are several parts that could be enhanced. These are e.g. the integration of the range extender mode that could be added to the auxiliary components instead of the driving modes. Another thing that should be reviewed thoroughly is the mixture of boolean and integer variables that are determine the driving mode. The current implementation goes for maximum flexibility but most likely more intuitive possibilities exist to solve this problem.

## Abstract

In this work, we use an acausal multi-domain physical system model to study the interaction between an internal combustion engine operation and a range of cooling scenarios. Although the model can be used for modelling a wide range of scenarios, in this paper we concentrate on the application of “thermal shock”. An internal combustion engine is load-controlled on a dynamometer and coolant temperature transients are imposed on the engine system. Using freely available and commercial Modelica Libraries within the Dymola environment, the whole system integration of the coolant rig and engine dynamometer is achieved. This allows the user to develop and define control strategies for the tests from desktop, prior to engaging in the real tests.

*Keywords: Engine testing, thermal-shock, control system development*

## 1 Introduction

Engines need to work under a variety of temperature conditions. Some engine failure modes are caused by temperature cycling which in turn causes thermal expansion and contraction. This phenomenon can induce mechanical stresses which in extreme cases can lead to component failure.

When an engine starts working it generates heat. This waste heat causes the engine components as well as the oil and coolant temperatures to rise. A thermostatic valve is used to ensure the engine and its fluids reach and maintain the optimum operating temperature for the duration of its use.

The thermostatic valve [1] remains closed during initial engine operation until the coolant temperature exceeds a set point. The thermostat then opens completely and a certain amount of cold coolant flows into the engine. Repeated hot/cold thermal cycles are the cause of the head gaskets failure.

If the cylinder head is kept cooler than the cylinder block, the block and the head will expand at different rates. These non-homogeneous head contractions and block expansions produce strain stresses on the head gasket. Even if the cooling system works well, repeated power on/off cycles will produce cracks on the head gasket surface. The head gasket is the most vulnerable part of any engine and a head gasket failure may result in catastrophic damage to the engine.

The non-homogeneous expansions and contractions of the engine block and head are especially significant with aluminium cylinder heads because aluminium expands approximately two times as much as cast iron when heated. The difference in thermal expansion rates between aluminium head and cast iron block combined with the stress caused by thermal cycles can cause the cylinder head gasket failure.

## 2 Thermal Shock Testing

Many manufacturers carry out thermal shock tests to understand and prevent component failure, as well as to accelerate durability testing of engines and engine components, including cylinder-head gaskets.

Thermo-mechanical fatigue is the term used to describe the type of fatigue in which temperature is varied through a cycle. The maximum tensile strain occurs at the same time as the maximum temperature. Maximum compressive strain occurs at the minimum temperature. The main factor causing thermo

mechanical failure is a large number of temperature cycles.

As in fatigue testing, it is possible to accelerate thermal cycling failure modes by increasing the frequency or amplitude of the thermal cycles. These thermal tests are used to simulate critical conditions inside the engine circulating a coolant flow with very large temperature gradients in short periods of time (e.g. 30°C to 120 °C). This is repeated cyclically.

The main task to be performed is to simulate repeated hot/cold thermal cycles. The engine is cycled between rated power and low idle. The coolant is also cycled between hot and cold respectively by means of an external conditioning unit.

**Figure 1:** Example of an engine thermal shock cycle. Engine speed shown in red and coolant outlet temperature from engine shown in blue (°C).

The temperature gradient in the warm up and cooling down cycles is critical to the mechanical stresses applied to the engine due to the thermal shock.

These kinds of tests allow manufacturers to reproduce the whole life of an engine in about 500 hours for a light duty passenger car and 2000 hours for a heavy duty vehicle.

Manufacturers expend great efforts in obtaining a good correlation between specific tests and the actual life time of an engine. Once the correlation is completed, the test must be performed as accurately as possible to preserve this correlation.

### 3 Necessity of a Simulation Model

The interaction of an engine cooling system and coolant over time leads to complex equations which need to be integrated versus time in order to predict the cooling and heating ramps the engine will experience.

Adding the thermal shock equipment responsible for the temperature cycle control increases the complexity of the problem.

The requirement to design a system capable of following a specific temperature profile over time with high accuracy, guaranteeing fast temperature gradients, implies the need to develop simulation models capable of dealing with this problem.

Existing simulation tools available within AVL (e.g. AVL boost) do not cater for multi-domain systems engineering where various systems performing different functions are integrated with one another. They are more specialised tools used for simulation particular types of system. When there is the need to simulate such diverse types of systems integration, Dymola through the Modelica language serves its purpose.

## 4 Case Study

A thermal shock unit is designed to test different Diesel engines with powers rating from 8kW to 150 kW and weights rating from 125kg to 556 kg.

Thermal shock must be performed measuring engine coolant outlet temperature and cycling from 30°C to 120°C.

### 4.1 Thermal Shock Equipment Concept

The equipment consists of two coolant tanks each with a capacity of 1500 litres. One tank is held at a high temperature (120°C) and one at low temperature (30°C). Two additional tanks installed in proximity of the engine and serve as an engine outlet pressure control. Pumps and valves control flow which is circulated and bypassed in the engine creating the thermal shocking of the engine.

**Figure 2:** Example of an engine thermal shock rig showing the main components and routing, including the equipment split between the technical floor and the test cell.

## 4.2 Thermal Shock Testing Equipment

The unit is divided in two main modules, one installed in the technical floor containing the main tanks.

**Figure 3:** Thermal shock rig (technical floor side) with hot (left) and cold (right) tanks.

A second one installed in the test cell with the switching valves and the pumps.

**Figure 4:** Thermal shock rig (test cell side) with test bed (blue), routing valves and pipes on the left.

## 5 Model Development

### 5.1 Engine Model

The engine model is based on the Claytex Engines library which offers a wide range of engine configurations and component detail scenarios [2], [3], [4], [5].

The engine model used in this example is a 2.2l common rail turbo-diesel inline 4 cylinder engine. It is a Mean Value engine model where the intake and exhaust air paths are modelled [6] as well as the emissions, pressure charging, torque generation and fuelling. The engine mechanics is multi-body in type utilising the efficient rotational 3d components from the Claytex library. The Claytex rotational 3d library components allow multi-body modelling with comparable computational efforts to a 1d mechanical system, and have been used throughout our projects.

**Figure 5:** Mean Value engine model with replaceable mechanical and fluidic subsystems.

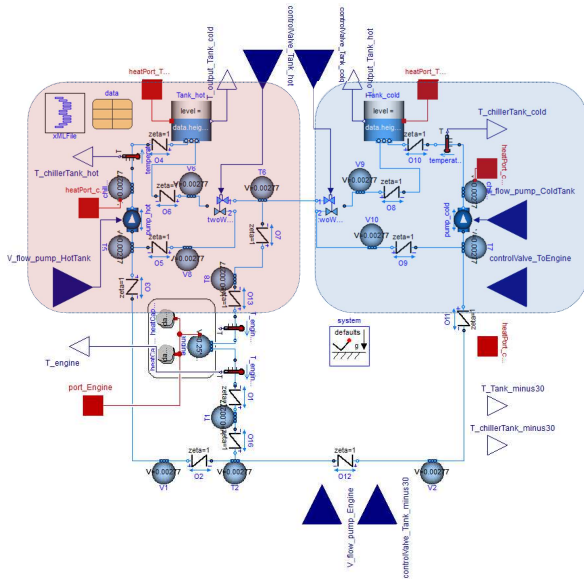

The engine is coupled to a torque based Engine Control Unit which specifies the fuelling and torque required but also controls ancillaries such as the turbo-charger wastegate.

The engine heat release to coolant has been defined as a fraction of the crank power and varies depending on engine speed and load. The fraction value is determined from steady state tests by calculating the power to coolant required for the coolant temperature change between the coolant inlet and outlet of the engine. The coolant path within the engine is represented by a single pipe having average diameter of the passageways and the measured total engine coolant pathway volume and surface area. The pipe diameter is adjusted to achieve the required coolant flow speed through the engine.

The engine thermal mass in this case is a lumped thermal mass and is not split by component. More detailed models are available within the Claytex En-

**Figure 8:** Thermal shock rig with hot (left) and cold (right) circuits.

The controllers for the tank heaters and coolers are of PID type and tuned to account for the power of these components and the response required of the system.

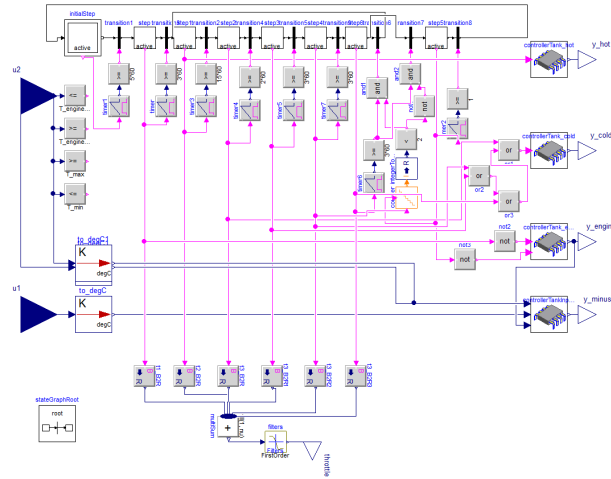

**Figure 9:** PID controllers for controlling the heat exchangers and heaters to maintain tank fluid temperatures close to the set-point.

If the tank fluid temperature has strayed from the set point, the heater and cooler and associated controller need to be sized and parameterised appropriately so that the set-point temperature can be restored prior to the next hot or cold cycle.

To control the 3-way valves a Modelica.StateGraph model was created (Figure 10). At particular points in the cycle the valves are operated to route the hot or cold coolant through the engine. The same State-

Graph model controls the throttle pedal position which is cycled from 0-100% in a similar phase to the engine speed (Figure 10).

The PIDs for the tank heaters and cooler control were optimised to achieve minimal deviations (1-3 °C) during the cycles.

**Figure 10:** StateGraph controllers for the 3-way valves.

**Figure 11:** Resulting accelerator pedal position (top) and engine speed (bottom) for the thermal shock test.

## 6 Results

The integrated engine and coolant rig, as shown in Figure 5, yielded close results to those measured on the test bed with some minor discrepancies on the

hot part of the cycle when the engine is operating at full power. We analyse the engine coolant in and engine coolant out temperatures as shown in Figure 12. Firstly we consider the accuracy of the inlet coolant temperature to the engine. If the temperature of the coolant at the engine inlet is not accurate then this will influence the exit temperature and potentially reduce the accuracy of the model. Discrepancy in the coolant inlet temperature after ramp up and ramp down ranges from 0.4-0.85°C. This type of error is deemed acceptable and demonstrates that the conditioning system is sized and modelled correctly.

**Figure 12:** Engine coolant inlet temperatures for test data (blue) and simulated data (red dashed).

Being satisfied with the coolant inlet results we now concentrate on the engine coolant outlet results. This is the coolant temperature exiting the engine. We notice the ramp downs (shown in Figure 13) at  $t \sim 250s$  and  $t \sim 650s$  are offset in time. Initially we get a faster cooling of the modelled engine but as the coolant temperature approaches the cold circuit temperature (27 °C) the modelled coolant temperature transient slows down. Nevertheless we note that the lower temperature is achieved prior to the coolant temperature increase ramps at  $t \sim 470s$  and  $t \sim 830s$ . On the temperature increase ramps the engine coolant heats up marginally quicker than the test shows and overshoots the test data at the higher coolant temperatures  $t \sim 600s$ ,  $t \sim 950s$  by approximately 0.3-1°C.

The high temperature sections correspond with the engine being at full load and speed. The overshoot tells us that there is excess heat being put into the coolant by the engine at maximum power in the model.

**Figure 13:** Engine coolant outlet temperatures for test data (blue) and simulated data (red dashed).

The minor discrepancy in the transients is believed to be linked to the correction required for heat rejection of the engine to the coolant and potentially the thermal mass of the engine itself.

The whole system model on average is shown to run faster than real-time with both variable (Figure 14) and fixed step (Figure 15) solvers, the latter making it suitable for hardware-in-the-loop simulation. For fixed step solver the target turnaround time is 1ms. There are occasional spikes denoting overruns (Figure 15) which can be accommodated for. Further improvements in event checking suppression should allow the reduction if not removal of these spikes.

**Figure 14:** Model performance using Radau IIA variable stiff solver for stiff systems showing Real time (vertical axis) vs. simulation time (horizontal axis).

**Figure 15:** Model performance using Euler fixed step solver and implicit inline integration showing CPU time per calculation step (vertical axis) vs. simulation time (horizontal axis)

## 7 Conclusions

This paper shows how a highly complex multi-domain system to reproduce engine thermal cycling scenarios such as “Thermal shock” can be created within Dymola. Detailed physical representation of the internal combustion engine as well as the coolant rig, valves and controllers has been achieved. The acausal and multi-domain properties of the Modelica language make it possible to simulate all these integrated systems within one larger system model without the need to interface with third-party tools.

Despite the model complexity it will run faster than real-time. Symbolic manipulation plays a large factor in this reducing the number of equations to be solved from in excess of 27000 to just over 3700.

The model will allow the user to specify and define appropriate components and control strategies used to test engines without actually having to use a real engine. This in turn reduces costs, pollutant emissions and the time involved in calibrating a rig and controller with the internal combustion engine fitted and run.

Lastly, the model has been shown to achieve real-time simulation with Euler fixed step solver and implicit inline integration making it suitable for HIL applications.

## Abstract

Increasing energy prices as well as outdated building systems present the housing industry with the challenge of finding new complex system solutions including renewable energy and storage systems. The municipality Lohmen and the local housing association contracted EA Systems and IB Dr. Lerche to develop an integrative energy system concept for its historic town center.

This paper deals with modeling and simulating different energy system variants for the existing building structure using the Modelica-based ‘Green Building’ library and SimulationX. The discussion illustrates the challenges of the modeling process, innovative solutions and the simulation results.

*Keywords: Green Building, Building Simulation, Building Quarters, Building Complexes*

## 1 Introduction

In Germany, most buildings were erected before any heat insulation regulations existed. Therefore, most of them had to be refurbished from time to time to reduce thermal energy consumption and to adapt to current legislative requirements (e.g. Energy Saving Ordinance).

Especially in the East of Germany, last region-wide refurbishment measures were taken back in the 90s of the last century. Hence, most buildings there still meet current energetic requirements. However, the building energy systems installed at that time have a lifespan of about 20 years. Consequently, building owners today, whether they are private or public, have to think about new refurbishment measures.

Conventional measures to replace existing, outdated heating systems with more efficient system components (e.g. gas-fired condensing boilers) contribute to a significant reduction of energy consumption. But rising energy prices and upcoming legislative requirements to reduce carbon dioxide emissions mean that these measures will not be sufficient. Innovative ideas, like integrating renewable energy systems and storages, have to be tested for applicability to specific building situations.

To meet this challenge, the municipality of Lohmen and the local housing association contracted EA Systems and IB Dr. Lerche to develop an integrative energy system concept for the historic town center. This requires local characteristics, especially the availability of renewable energy, to be scrutinized. In this regard, suitable energy system variants have to be derived and evaluated for energy efficiency, economical requirements and further ecological aspects.

The given complexity requires new analytical methods. The availability of renewable energy has to

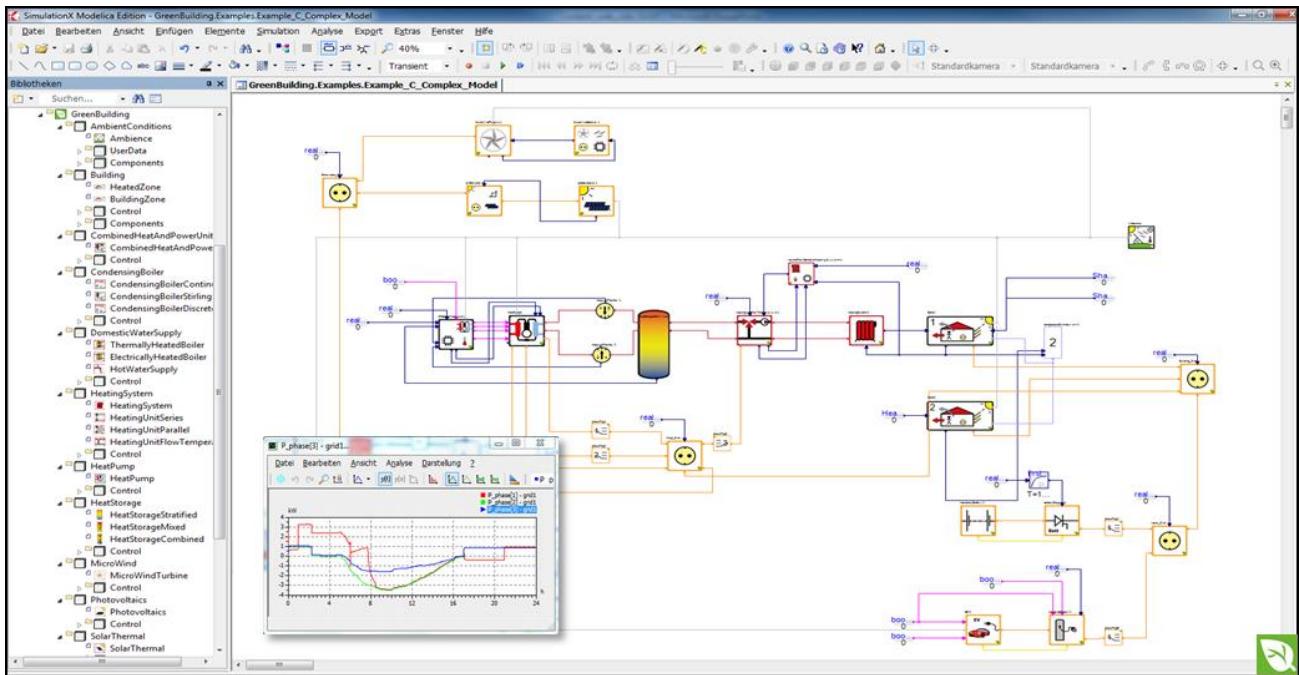

Fig. 1: Modelica model of a renewable energy system incl. the building in the simulation environment

be analyzed in combination with strongly usage-dependent energy consumption profiles as well as state-specific applicability of partly new storage systems (e.g. batteries). For that reason, only dynamic simulations of different energy systems can provide sufficient results for an adequate system evaluation.

As a newly developed simulation environment, the Modelica-based ‘Green Building’ library and SimulationX were used to fulfill the given engineering task. Since it was developed especially for such applications, ‘Green Building’ can be used to easily model complex energy systems including renewables, storages as well as complex building structures in one simulation environment.

## 2 Green Building Simulation Library

Modelica is an equation-based and cross-domain modeling language. It offers the possibility to model complex building energy systems with different domains (e.g. heat, electricity, control) using differential-algebraic equations. These equation systems can be edited and solved within one simulation environment.

That is why EA Systems used Modelica and the versatile CAE tool SimulationX to develop the ‘Green Building’ library for the simulation of energy systems [4]. By adapting an approach widely used in the automotive industry, several elements for the production of renewable energy and heating systems

were created as well as storages and electrical or thermal consumers [5]. Most of the models represent real world objects like vehicles, electrical inverters or valves. Granularity and complexity of each element are thus in the same range while preserving a flexible yet easy modeling process (i.e. physical as well as phenomenological models [5]). The modeling focus lies on the interactive behavior of different energy system components with varying complexity in the context of building energy supply, be it thermal or electrical (i.e. electrical systems modeled using RMS values [4]). Although the building itself can be modeled as a complex thermal and electrical energy consumer by using a number of thermal zones, a detailed thermal building simulation for different thermal conditions in one room, for example, requires a more specialized tool, like EnergyPlus (Green Building, for example, uses constant average temperatures in thermal zones [5]).

Figure 1 shows the ‘Green Building’ simulation environment in ITI’s SimulationX with a relatively simple model of a single-family home including a heat pump as well as a micro-wind turbine and a photovoltaic system as renewable energy sources [6].

## 3 Municipal area of Lohmen

The surveyed area in the municipality of Lohmen, a small town in the middle of the Free State of Saxony in Germany, includes altogether twelve buildings

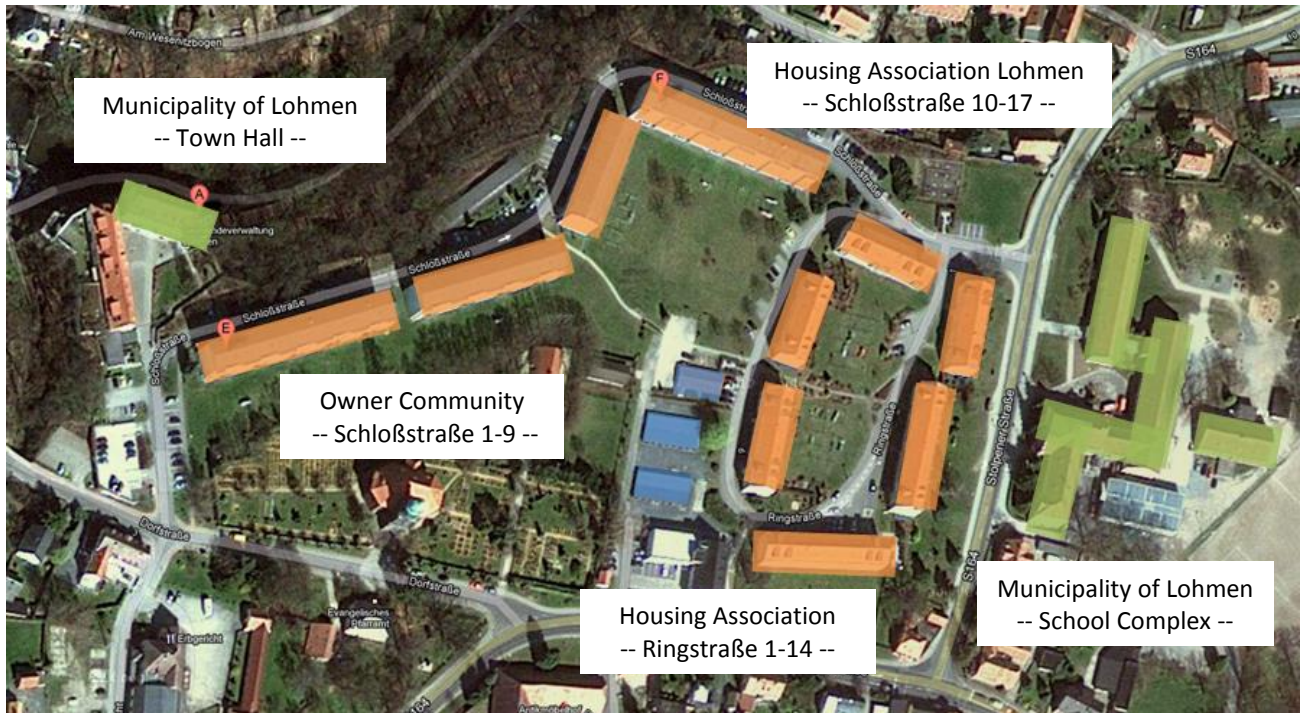

Fig. 2: Historic town center of Lohmen

and building complexes. Besides ten dwelling houses built in the 1960s and 70s, there are also the over 500-year old Lohmen castle, the office of municipality, as well as the school complex with four separate buildings which are part of the study.

Figure 2 shows the historic town center of Lohmen with all acting partners, its municipality, the housing association as well as a local owner community.

Intensive analyzes of available energy saving potentials and existing renewable sources were the basis of the following modeling and simulation work. Initial analyzes dealt with conventional refurbishment measures of existing heating systems and the usage of solar energy. Besides, Lohmen is directly situated at the river Wesenitz with a number of existing water power plants in the area of the historic town center. Hence, further analyzes mainly revolved around the integration of water power as well as water heat usage with heat pumps, for example.

## 4 Modeling paradigms and simulation results

Basically, energy can be provided in two ways. Heat and electricity can be supplied to each house individually. That means heat is produced by internal heating systems, like condensing boilers or micro-cogeneration units. Electricity can be taken from the grid or from locally installed photovoltaic systems

on each building's rooftop. These basic approaches are single-building solutions which only replace or modify existing building energy supply concepts. That way, existing renewable energy potentials (e.g. river water heat) cannot be used in an economic way.

Other solutions consider all existing buildings together. These quarters solutions enable an economical use of all available renewable energy potentials as well as existing synergy effects, e.g. electricity production with photovoltaic systems only on rooftops facing South.

Basically, SimulationX' 'Green Building' library was used to implement and to simulate adequate system models. This simulation environment enables the user to simulate variable building energy systems including a building's heating as well as the inhabitants' electricity consumption. The basic modeling idea though was a single-family home. That required some modifications of existing models and the development of new, adequate modeling approaches for the project at hand.

Figure 3 shows two of these newly developed modeling paradigms. The model on the left shows the school complex which consists of four building models for each part of the complex (elementary school, kindergarten, gym, historic school). Each of these building models is implemented as three 'Building Zones' from the 'Green Building' library representing basement, classrooms and roof. Furthermore, the school complex model includes domestic water production, electricity consumption as

Fig. 3: Sub-model structure of the school complex and the heat pump cascade

well as heating system components (e.g. valves, pipes, etc.).

The right side of figure 3 shows the implemented sub-model of a heat pump cascade to be used as a basic heating system for the quarters. It consists of ‘Green Building’ heat pump models including connected controllers as well as heat storages. Furthermore, a river model provides information about available water heat and renewable electrical power of existing water power plants. Heat supply to the district heating grid is represented by a convenient heat exchanger model.

Both modeling approaches illustrate the basic modeling idea used during this project. Buildings and usage (domestic water consumption, electricity consumption, etc.) are implemented individually in sub-model components. That way, they can either be used for single-building simulations or for entire quarters simulations without the need for further model adaptations.

#### 4.1 Single-building simulation

The following energy system configurations including renewable energy usage were examined in single-building analyzes:

- Condensing boilers
- Micro-cogeneration
- Photovoltaic systems
- Solar thermal collectors
- Gas-fired heat pumps with geothermal energy usage

The replacement of existing condensing boilers always represents a basic strategy to lower natural gas consumption of each building. They are able to provide heat for buildings and domestic water supply at fairly high efficiency rates (higher than 95%). Adding small micro-cogeneration units to each building’s energy system allows for a combined heat and electricity production. That way, general electricity consumption, e.g. for heating pumps and hallway lighting, can be significantly reduced. Especially in Germany, cogeneration units are substantially subsidized by the state. Hence, heat and electricity can be produced at relatively low operating expenses.

Fig. 4: Specific renewable heat production of different solar collectors at different residential buildings

Photovoltaic systems provide renewable electricity to meet a building’s general electricity demand. In Lohmen, general electricity consumption is rather low. Therefore, local electricity production has to

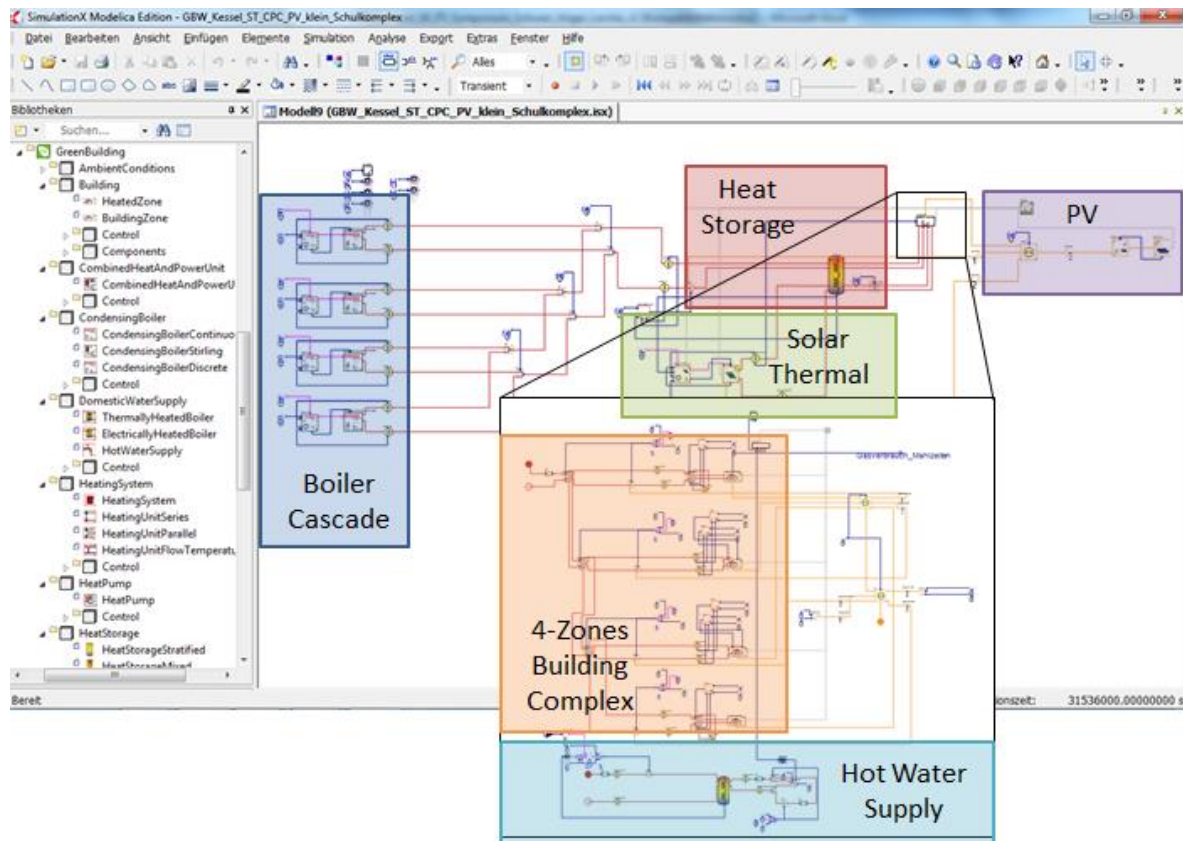

Fig. 5: Single-building model of the school complex with condensing boiler cascade, heat storage, solar thermal collector and photovoltaic system

account for these conditions. The inhabitants' electricity consumption is much higher, but cannot be met easily by local electricity production, because of German tax legislation for housing associations. Furthermore, electricity fed into the grid is not very profitable for newly constructed energy systems. Consequently, the main goal of energy system design is to minimize the amount of electricity fed into the grid while maximizing the production of renewable energy.

Solar thermal collectors constitute another energy system configuration that uses solar energy as a source. They can provide a significant amount of a building's domestic water consumption if they are installed in the right spot (e.g. south facing roofs). However, there are two different types of collectors: flat plate and CPC (Compound Parabolic Concentrator) collectors. Figure 4 shows some sample results from simulation-based analyzes of the solar thermal energy potential of various residential buildings' roofs. CPC collectors always represent a more efficient system variant. Due to quite high system costs, a specific heat gain of at least  $250 \text{ kWh/m}^2$  is needed on average. Figure 4 shows that only CPC collectors on buildings with south facing roofs (e.g. Schloßstr. 13-17) can provide enough solar energy input for the

analyzed system configuration (domestic water production with hot water boilers at  $60^\circ\text{C}$ ).

The third energy system configuration that was simulated and evaluated for each single building is based on gas-fired heat pumps. Compared to electric heat pumps, these comparatively new systems provide heat using geothermal energy as well as a smaller amount of natural gas.

Figure 5 shows a complete single-building model of the school complex with a condensing boiler cascade as a basic heat supply system, solar thermal collectors to support domestic water supply, and a photovoltaic system to provide renewable electricity. This sample model shows only one of nine simulated and examined system configurations for the school complex:

- Existing building with two 15-year old condensing boilers
- Refurbished energy system (e.g. increased pump efficiency) with some adaptations of the building insulation
- New condensing boiler cascade with modulating working burners
- Condensing boiler cascade with small Stirling CHP
- Condensing boiler cascade with CHP

- Condensing boiler cascade with solar thermal system (CPC)
- Condensing boiler cascade with CPC collectors and small photovoltaic system
- Condensing boiler cascade with small photovoltaic system
- Condensing boiler cascade with large photovoltaic system

Figure 6 shows results for simulated electricity and natural gas consumptions of the school complex' analyzed system configurations.

Fig. 6: Simulation results for different system variants of the school complex

All results are compared against the results of an existing old condensing boiler cascade. All variants, except for the existing system, are simulated with simple refurbishments of the building's heat transfer system (e.g. pumps) and the building's insulation. It is evident that even simple refurbishment measures have a significant impact on the heat and electricity consumptions. However, variant 3 with the new condensing boiler cascade is the first energy system variant suitable for long-term decisions due to the age of the existing boiler.

Furthermore, it appears that system variant 5 with a large combined heat and power unit (CHP) could be the most interesting variant regarding energy consumption and system efficiency, because the electricity consumption can be reduced significantly without increasing the natural gas consumption too much.

All in all, over 70 variants of different energy system configurations and different buildings were modeled and simulated using the 'Green Building' library and further presented modeling paradigms. Such energy supply variants for single-buildings, however, have only limited potential to reduce the renewable energy usage and energy consumption. Further analyses have thus been conducted regarding a number of different energy system variants for the entire quarters.

## 4.2 Simulation of the Quarters

The basic idea is to combine all implemented building models (see right part of fig. 3) of ten residential buildings, Lohmen castle and the school complex into one large simulation model plus various energy system configurations. The main part of the heat supply regards a district heating grid implemented with 'Green Building' components. This district heating grid includes volume flows as well as temperature behavior in single pipes to enable dynamic heat loss simulations (i.e. simulated heat losses to ground using a static ground temperature model [7]). The layout of the circulation pump, however, (regarding pressure drops, for example) is configured during preprocessing in order to reduce the number of simulated system states.

Figure 7 shows a sample district heating grid model with several centrally located condensing boiler cascades, a heat pump cascade using river water and water power plants as heat and electricity source as well as two cogeneration units for overall domestic water supply located in the school complex.

Two different types of district heating grids were implemented and analyzed. A "small" district heating grid provides heat from two cogeneration units to meet domestic water requirements of each building. Mechanical space heating is still provided locally by several condensing boiler cascades.

The "large" district heating grid solution includes cogeneration for domestic water supply as well as main heat power production by a 520 kW heat pump cascade. Heat pumps use river water as environmental heat source and electricity produced at local water power plants as electricity source. Both heat sources are connected to each building via a widespread district heating grid. Further heating power demands are met by smaller peak-power condensing boiler cascades.

Modifications can be done by adding further, smaller photovoltaic systems. Additionally, some of the implemented condensing boilers can be replaced by gas-fired heat pump systems again. That way, the system can be optimized with respect to number and type of the required components.

Such a complex energy system requires sufficient control algorithms to operate the appropriate system components. That way, standby losses of system components that are not in use (e.g. peak power condensing boilers at higher ambient temperatures) can be significantly reduced. Furthermore, renewable energy usage can be increased by avoiding simultaneous heat pump operation, for example.

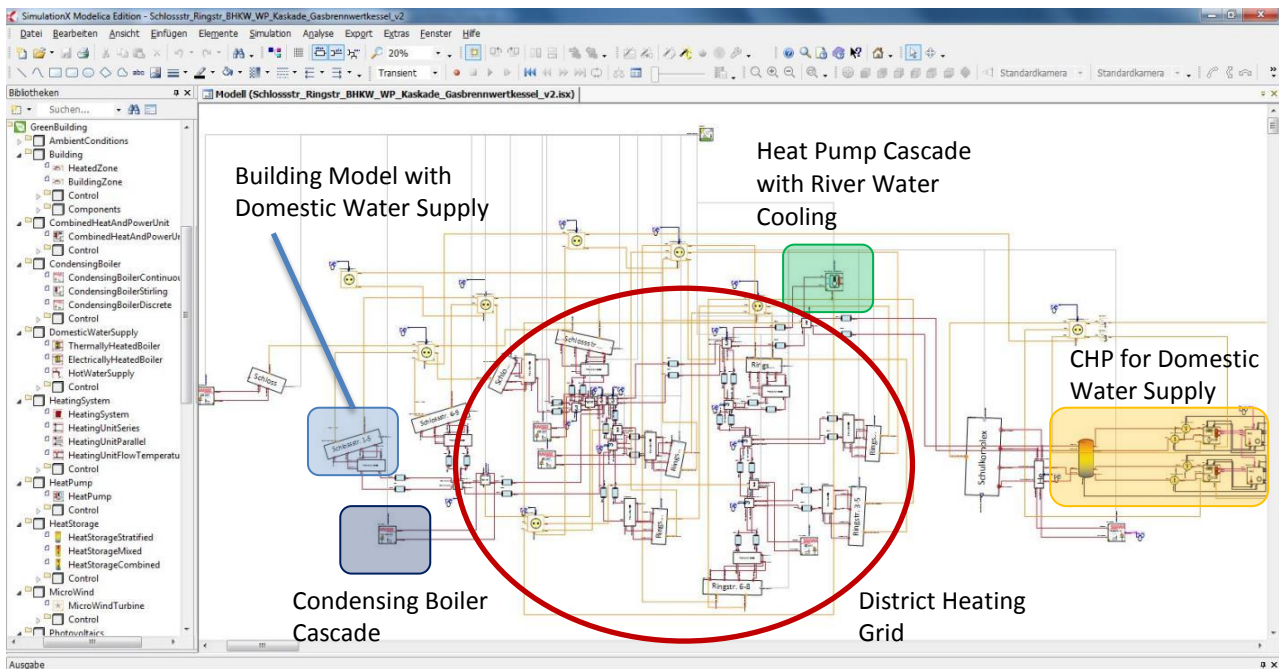

Fig.7: Simulation model of the quarters with district heating grid, micro-cogeneration, heat pump cascade, peak power condensing boiler cascades and all involved building complexes

‘Green Building’ enables the user to implement physical energy systems as well as corresponding controller behavior (mostly P controllers with hysteresis switch-on/off statements) in one large simulation model within the SimulationX modeling environment. Previously presented optimization tasks can thus be executed more easily.

Each of the two types of energy system configurations for the district heating grids were simulated with four and five different system component configurations and/or control algorithm sets. All results were evaluated in comparison with the buildings’ existing energy supply infrastructure and the accumulated results of single building simulations with condensing boilers as the basic heat supply variant.

The simulation’s result analysis focused on the affordability of different energy system components. Cost analyses, however, are not a basic part of the ‘Green Building’ simulation environment. Further result evaluations revealed some interesting aspects regarding energy saving potential as well as overall system sustainability.

Figure 8 shows simulation results for the relative overall energy consumption of each simulated system configuration, divided into natural gas and electricity consumption.

The diagram is divided into three basic parts. The left side shows accumulated results of all analyzed single-building simulations. It illustrates the overall energy consumption of the quarters’ existing energy systems, simply refurbished energy systems as well as the basic “energy-concept” regarding the replace-

ment of old boiler systems by new condensing boilers.

The second part of the diagram shows results for the previously introduced “small” district heating grid variant. Besides basic system configurations, it was also simulated with a 14.5 kWp photovoltaic system on a suitable building roof. Furthermore, the integration of street lighting into the overall energy system concept was part of some analyses, and some of the integrated condensing boilers were replaced by new gas-fired heat pump systems.

Most simulations for the quarters’ analyses were run for a second district heating grid system variant. This “large” variant mentioned earlier includes a heat pump cascade for main heating power supply. It was simulated with and without recognizing street lighting. However, most of the simulated results concern different optimization levels of energy management system.

On the one hand, basic energy management system algorithms forced the CHP cascade to provide heat for domestic water supply in residential buildings even in winter months when sufficient heat power is directly needed in the school complex. On the other hand, all peak power condensing boilers stay activated even in case of ambient temperature levels above the estimated bivalence point. Furthermore, all heating systems, even the heat pump cascade, are operated at comparatively high flow temperature levels.

Evidently, the system does not work in an optimal way. Therefore, some optimization steps were taken

Fig.8: Simulation results of different energy system variants for complete quarters solutions

to improve the implemented energy management algorithms. First of all, the condensing boiler cascades were shut down in case of ambient temperature levels rise above the bivalence point. Furthermore, the CHPs are only used to provide residential buildings with domestic water in transitory and summer periods. These measures are shown as optimization level 1 in figure 8.

Optimization level 2 refers to the reduced operation of the heat pump system during the summer months. Heat pump systems are supposed to provide heat only to connected buildings. However, they are not intended to provide domestic water because of required higher temperature levels. Lowering the heat pump cascade thus reduces standby losses without affecting any heat power needs.

The third optimization level refers to reductions of preconfigured reference temperatures for all implemented heating system components (i.e. heat pump cascades, peak-power condensing boilers). That way, reference temperatures could be reduced by about 5K to enable all components to run in better working ranges (e.g. COP of heat pumps).

The last optimization level affected only switch-on and switch-off times of the planned heat pump cascade. In the planned “large” district heating grid system variant, all heat pumps are equally used to

provide heat (c.f. Tichelmann system in fig. 3). All previously presented energy management algorithms forced each heat pump to work mainly at the same time (i.e. control hysteresis was implemented in the same way). Hence, this control regime was adapted to sequentially drive the heat pump cascade. This way, electricity provided by the water power plant can be used more efficiently to power each heat pump. That enabled a reduction of the overall electricity consumption.

Both variants of district heating grids offer massive reductions of energy consumption and a better use of available renewable energy. The “small” district heating grid variant provides huge reductions of electricity (ca. 80%) consumption even in comparison to refurbished single-building system variants. This is mainly caused by comparatively huge amounts of electricity produced by the CHP system. However, the overall natural gas consumption increases slightly because of partly simultaneous heat and electricity production.

The “large” district heating grid shows opposite results. Using environmental energy as well as electricity to provide heat massively decreases the natural gas consumption (ca. 50%). However, existing power plants cannot generate all electricity required for the heat pumps’ operation. Hence, the overall

Fig.9: Pictures of residential buildings (top left), historic school (bottom left) and ancient Lohmen castle (right)

electricity consumption can even exceed the existing electricity demand. Apparently, system optimization as well as iterative improvements of implemented energy management algorithms can sufficiently decrease these effects.

Finally, both district heating grid solutions provide extensive reductions of energy consumption. This is mainly achieved by using huge amounts of renewable, environmental energy (e.g. water power) as well as synergies in the existing quarters. That way, providing electricity, which is produced by a newly installed CHP system, to street lighting would further decrease overall electricity consumption in a significant way.

Furthermore, replacing some of the additionally needed peak-power condensing boilers by an adequate number of gas-fired heat pumps using geothermal energy as additional heat source can significantly improve natural gas consumption as well.

## 5 Conclusions

This paper shows how the SimulationX ‘Green Building’ library was used to analyze and to evaluate different suitable building energy system variants of building quarters in the historic town center of Lohmen. Some selected modeling paradigms are presented to demonstrate how to use ‘Green Building’ for simulating larger building complexes.

Furthermore, the developed analyses approach, be it the comparison of different energy system configura-

tions for single buildings or the evaluation of the given quarters as one unit, is presented as well.

Some simulation results are illustrated for one single building evaluation process regarding the school complex. In comparison to that, both developed energy system variants representing a district heating grid are introduced with their specific characteristics. Simulation results are evaluated in comparison to single-building analyses. Advantages and disadvantages of both variants and derived system configurations are discussed at the end.

The simulation models are relatively complex. The simulation of a single building energy system took 0.5 to 4 hours for one year. In comparison to that, simulations of the quarters took between 3 and 4 days to finish. It is thus evident that ‘Green Building’ can be used to economically analyze complex variants of building energy systems. Parallelization by using multi-core computing can further improve this aspect.

Extensive engineering efforts yielded a comparatively high numerical stability of the Green Building library [6]. That way, simulating even complex, coupled numerical systems (linear and nonlinear) does not affect convergence. The presented project, for instance, comprised complex quarter models with up to 3000 system states. Simulating these models for one year causes around one million event iterations.

The presented results are part of a research study which is funded by KFW (Development Loan Corporation) and communal as well as private investors. The complete research project includes theoretical,

simulation-based analyses of sufficient energy system configurations. First approaches as well as initial simulation results were also shown in [3]. Acting partners (c.f. fig. 2) can decide which energy system variant meets their predefined requirements best with respect to affordability and sustainability. The chosen energy system variant will be built in a second project part beginning in the middle of 2014.

## Abstract

In this study, the possibility to interface a commercial building simulation tool with Modelica models is investigated. In this application, the zonal model VEPZO – modeled in Modelica – is coupled to the software TRNSYS – mainly programmed in Fortran – to be able to perform a dynamic co-simulation. The objective of this coupling is to obtain refined airflow and air temperature prediction, while retaining computation effort low enough to allow for transient computation. In a first attempt, a coupling using FMI was tested without success due to a lack of adequate solvers for FMI export. Therefore, a script coupling was implemented. Further steps include a validation and evaluation of the programmed interface and the results of the coupled system in respect to computation time, quality of results, usability and further development.

*Keywords: building simulation; zonal model; FMU, Dymola scripting, TRNSYS*

## 1 Introduction

Building simulation tools are used to assess building energy consumption, building control strategies, system performances, etc. on an annual or longer basis. In Modelica, the Buildings Library [1] and the Indoor Climate Library [2] contain models for the simulation of building energy performance. These libraries allow the simulation of building models directly in Modelica. Beside these, various commercial and free non-Modelica building simulation software products are available on the market. User's experience, knowledge of a specific tool and availability of tools in companies and institutes determine which

software is used. Therefore coupling of different tools becomes interesting when a specific model reaches its limits. In the presented study, an interface has been established for TRNSYS and the VEPZO model [3; 4] (programmed in Modelica) in order to enhance the simulation of atria.

### 1.1 TRNSYS

TRNSYS (Transient Systems Simulation) development started at the University of Wisconsin in 1975. The latest version 17 was released in 2010. TRNSYS code has a modular approach and is structured into types. Each type contains code for a specific task, usually representing a model of a specific component such as a part of an HVAC system. Types have a common structure and communicate via a given set of inputs, outputs and parameters. A central type for building performance simulations is the multizone building simulation environment (Type 56). It subdivides a building into multiple zones with homogeneous properties and conditions. The computation includes heat flows due to radiation, convection, conduction and solar gains and enthalpy flows through ventilation and air leakages. The integrated code COMIS [5] allows the formation of an airflow network by interconnecting zones. A schematic setup of the physical phenomena in an atrium is shown in Figure 1.

Figure 1: Schematic atrium model

The assumption of a perfectly mixed zone reaches its limits when simulating atria, because solar heat gains through glazing and a considerable height lead to thermal stratification of air. The current solution method to simulate atria in TRNSYS is to subzone them. For this, several air nodes are created in the atrium connected to one another by a predefined mass flow. To set up the model properly, the modeler requires prior knowledge of the airflow pattern – either from experience or from CFD simulations. However, even experienced modelers may fail to provide the proper airflow pattern. Due to a high requirement in computational power, CFD simulations are currently applicable for only a few configurations of different boundary conditions and only under steady-state conditions. Therefore, the extension of TRNSYS by a simpler airflow model is of interest.

## 1.2 VEPZO

The velocity propagating zonal model (VEPZO) was developed to fill the gap between the computationally cheap but inaccurate assumption of perfectly mixed air volumes and the slow but accurate CFD computation. Typically, a space is subdivided into  $10^1$  to  $10^2$  zones exchanging air [6]. The main components are a zone and a flow model which are connected by ports (Figure 2). Zone models possess a heat port to exchange convective heat flows from walls, equipment, humans, etc. In the zone model, conservation of energy and mass are implemented.

The flow model computes the airflow between adjacent zones resulting from pressure, momentum and height differences and losses. Velocity information is propagated through the models allowing the prediction of temperature and velocity distributions without prior knowledge of the airflow pattern. Models from the Modelica.Media package are used to compute air properties. Dymola is used as compiler for VEPZO. Results of the VEPZO model are the airflow pattern and temperature distribution in the considered space. Hence, it is suited to give a quick estimation of flow and air temperature conditions in an atrium.

Figure 2: VEPZO model in x-z direction (y not shown); cubes: zones; grey rectangles: flows; rhombs: airflow ports; red solid squares: heat ports.

## 1.3 Model coupling

TRNSYS and VEPZO are coupled to benefit from the respective strengths of the codes. The goal is to obtain a correct simulation of the energetic performance and climatic conditions in an atrium without prior knowledge of the airflow pattern.

TRNSYS has already been used for co-simulation with other tools such as ESP-r, Energy-Plus and Matlab [7; 8]. All couplings use TRNSYS as a master and exchange data through a TRNSYS type which translates data into the required format.

For the coupling of Modelica models to other simulation environments several possibilities exist. A powerful tool is the Building Control Virtual Test Bed (BCVTB), an interface for building simulations developed by the Lawrence Berkeley National Laboratory. It already provides an interface for Modelica and TRNSYS. However, the coupling currently does not allow for iterations between components

[9]. Therefore, it is not suitable for a dynamic co-simulation as envisaged in this application.

In recent years the FMI-standard has been established for model exchange with other software environments [10]. It has already found several applications in building simulation technology [11] and is especially suited for Modelica models. Another possibility to couple other software to Modelica (Dymola) is the use of script files in the .mos-format which are automatically created and whose execution is launched in the command processor.

## 2 Method

TRNSYS and VEPZO communicate at the inner wall surface of the investigated atrium where TRNSYS passes the wall surface temperature to VEPZO. With this information, VEPZO computes the heat flow rate from the wall to the adjacent zone and hence resulting airflow and air temperature distributions. The heat flow rate is returned to TRNSYS to compute the energy balance (Figure 3). This coupling is iterated until the total energy balance converges below a defined threshold.

Figure 3: Heat flows and temperatures computed by the two interfaced tools

Both TRNSYS and the Modelica model VEPZO required some preparation before being interfaced. TRNSYS air nodes, which are required in the simulation environment, are inactivated by setting convective heat transfer coefficients to zero. The convective heat flux is then replaced by the one obtained from VEPZO.

VEPZO required TRNSYS convective heat transfer correlations to be implemented in the model. Input and output connectors were included to receive the surface air temperature and to deliver the heat flow.

Furthermore, supply airflow rate and temperature as well as exhaust opening pressure were set as inputs.

### 2.1 Model coupling via FMI

First attempts to simulate VEPZO as an FMU showed that in spite of having set input values for air temperatures and pressures, the FMU instantiates with all inputs being zero. This generates an error in the air model from Modelica.Media as 0 K and 0 Pa are out of definition bounds. Therefore, temperature and pressure offsets were introduced in the model (273.15 K, 101325 Pa, Figure 4). Thus, the temperature input is in °C and the pressure input gives the deviation from standard pressure.

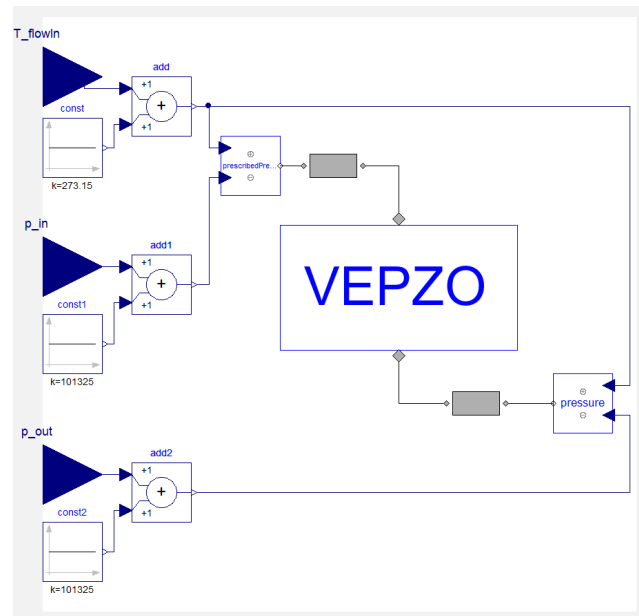

Figure 4: Introduction of temperature and pressure offset prior to FMU export

To allow the import of a VEPZO-FMU to TRNSYS, the new TRNSYS type was implemented (Figure 5). At the very first call the new type checks that the given FMU is suitable for co-simulation, retrieves the reference values of input and output parameters of the model and opens a result file which can be continuously accessed during the simulation. Then, the following steps are iterated:

1. Receive input values and current time as well as time step size from TRNSYS
2. Load the VEPZO-FMU
3. Instantiate VEPZO-FMU
4. Load values from the previous time step from internal storage
5. Initialize VEPZO-FMU with values from the previous time step

6. Perform calculation from the current to the next time step
7. Write results
8. Pass output values to TRNSYS.

Figure 5: Basic structure of the two coupled tools in the interface via FMI

The coupling was implemented and simulation time showed to be significantly prolonged in comparison to VEPZO simulations in Dymola. When simulating a simple test case with a supply mass flow rate of 0.1 kg/s, supply temperature of 10 °C and wall temperature of 30 °C the air temperature predicted by the FMU showed an unstable range between 180 s and 500 s simulation time in comparison to the simulation in Dymola (Figure 6). The reason for this is that VEPZO requires a fifth-order stiff Runge-Kutta solver in order to be solved for low supply mass flow rates. This solver is not available for export in the current version of Dymola, but will be implemented in future versions [12]. Hence the dynamic coupling of TRNSYS and VEPZO via FMU was discarded in this study.

Figure 6: Comparison of Dymola and FMU simulation of a simple test case in VEPZO

## 2.2 Model coupling through scripting

In a second approach TRNSYS and VEPZO were coupled using Dymola scripting. For this, another new TRNSYS Type was implemented. This type writes and executes a .mos-file containing wall temperatures, simulation settings and code for export of computed wall heat flow rates into a .csv file. The new type reads the .csv file and uses it as input for the thermal building simulation (Figure 7).

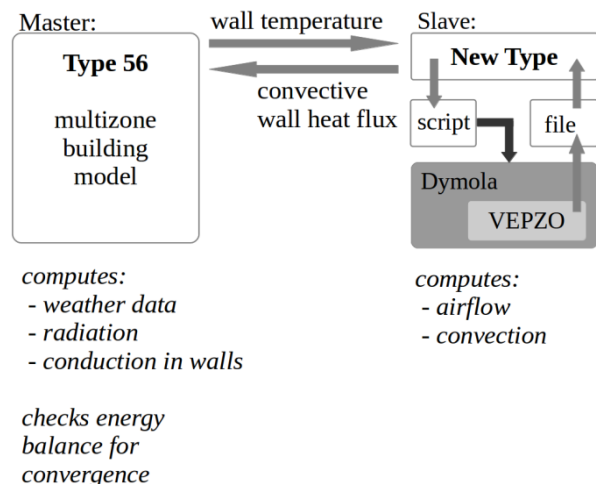

Figure 7: Basic structure of the two coupled tools in the interface via scripting

### 3 Atrium model

To demonstrate the coupled simulation of TRNSYS and VEPZO an atrium is modeled and simulation results are compared to data from measurements and CFD simulations. The modeled atrium (Figure 8) is part of the Concordia University engineering building located in downtown Montreal (45.5°N, 74°W). In total, five atria each covering three floors are placed on top of each other. The considered atrium is of rectangular geometry and can be conditioned by both natural and mechanical ventilation. Mouriki [13] conducted measurements in this atrium at four days ranging from August to November 2007. Based on this data, Hussain [14] carried out several CFD simulations of this atrium with different turbulence models.

Figure 8: Considered atrium

To reduce the uncertainty of boundary conditions, a day with only mechanical ventilation (November 2<sup>nd</sup> 2007) has been selected for comparison. It was a clear and cold day with ambient temperatures between -1.5 and 8 °C. The maximum global horizontal radiation for a nearby weather station was 480 W/m<sup>2</sup> [15]. Measurement readings are available from 6am to midnight. Figure 9 shows the geometry of the considered atrium and the location of mechanical ventilation inlet and outlet. The atrium air volume is divided into 5 x 5 x 6 (length, depth, height)

VEPZO zones. To compare the coupled simulation to the classical TRNSYS approach using modeler's experience, a second simulation model using only TRNSYS was set up. In this model, air is subdivided into three horizontal slices. Walls are discretized into a total of 20 facets in order to account for different wall temperatures due to varying solar radiation. For this work, we could not access construction plans of the atrium. The only hint to guess materials are published pictures and transient temperature measurements. Therefore, this information presents a considerable source of error which is mainly reflected in the thermal capacity of the system.

Figure 9: Geometry of considered atrium

The boundary conditions obtained from measurements are inner glazing surface temperatures, transmitted solar radiation, ambient temperature and supply air conditions (Figure 10). To acquire a proper initialization of wall temperatures, four days prior to the considered day were simulated before the coupled simulation was started. The coupled simulation took 4hr and 45min.

Figure 10: Supply air boundary conditions

Figure 11 shows the comparison of measurement and coupled simulation for the average temperature in three heights of the atrium. Five main observations are made:

- The results from the coupled simulation show an initial drop in air temperature which causes the further temperature profiles to be lower than measured.
- The peak in temperature is reached by about one hour delay in the simulation but shows good coherence in the absolute value with the measured peaks.
- The model is more sensitive to a change in airflow boundary condition than measurements show.
- A raise in temperature due to a lower cooling flow rate around 6.30pm can only be observed at the lowest measurement position but is observed for all heights in the simulation. The same is the case for the shut-down of the ventilation around 11pm.
- As a result, the air temperature at the end of the simulation is about 2 K higher than measurement shows.

Figure 11: Temperature at three different heights over the course of one day

Figure 12 shows a comparison of measured air temperature profile, coupled simulation results and CFD simulations [14] for 4pm. The coupled simulation shows considerably better agreement to measurements than CFD simulations do.

Figure 12: Comparison of simulated and measured temperatures over the height at 4pm

## 4 Discussion

The higher rate of response of air temperature of the model to variations in air supply suggests that it does not contain enough thermal capacities dampening variations of boundary conditions or that the convective heat coefficient model is inaccurate. Additional capacities can for example be caused by furniture and other internal objects like stairs. The initial drop in temperature implies that the surface's temperatures are lower in the simulation than they are in reality. This could be caused by a lower thermal mass of walls in the model or because the atrium gains energy from surrounding rooms during the night.

Between 3 and 4pm relatively stable temperature conditions are present in the atrium. For this case, the coupled simulation gives better results than CFD computations. The reason is that it is very difficult to obtain a good prediction of airflow by CFD for such large volumes with comparatively small openings without an adequate benchmark case.

The results from the dynamically coupled simulation in comparison to those obtained from a TRNSYS simulation show that very similar temperature profiles can be achieved for simple configurations where the airflow pattern can be predicted by experience. This implies that VEPZO results show a high dependence on the inputs obtained from TRNSYS.

## 5 Conclusions and future work

A dynamic coupling of the building simulation tool TRNSYS and the Modelica model VEPZO has been implemented successfully using Dymola scripting. A coupling through FMI was not successful due to missing solvers for FMI for co-simulation export.

The results obtained from the dynamically coupled simulation show significant dependence on the TRNSYS model, especially on the proper knowledge and implementation of the building construction (materials, capacities, etc.). If those are modeled accurately, coupled simulations can give good predictions of airflow and air temperature as required in the building planning process. In comparison to CFD, results of the coupled simulation show better coherence with measured data.

The usability of the current coupling method should be improved by speeding up computation times and facilitating geometry specific scripting. It could be increased by using FMI once the required solvers are available for export. It would be helpful if FMI instantiation could be performed at values different

from zero to avoid error-prone preparation of the Modelica model.

Further development of VEPZO as deduced from this study includes the implementation of heat transfer correlations which take into account the wall orientation and flow velocity. Additionally the feature of an artificial internal heat capacity will be integrated in order to be able to model furniture.

Regarding the interface, a possible further development is the integration of the multi-zonal model COMIS into the interface such that boundary conditions at atrium openings can be obtained from a coupled COMIS-TRNSYS simulation. Once the computation time of the coupling is reduced, the interface could moreover be utilized to optimize the design of atriums and large halls such as the best location and size of ventilation openings.

## Abstract

This paper presents the Modelica Thermal Model Generation Tool. The aim of this tool is to enable the user to set up a geometrically correct thermal model for complex geometries that allows predicting the impact of heated/heating devices and their location both in terms of airflow pattern and radiation distribution. Using a geometry file exported from CAD software, the tool distributes wall facets, air nodes and computes the long-wave radiant view factor matrix for obstructed and unobstructed surfaces. This information is exported as ready to use Modelica code. The zonal model VEPZO is used to model airflow within a domain (enclosed space). This model allows predicting airflow and air temperature distribution in space on a coarse mesh and thus computes faster than classical CFD computations. Walls are subdivided on the same grid as the zonal model is set upon. For each wall facet, the Modelica Thermal Model Generation Tool computes the view factors to the other facets in the domain.

Comparison of simulated results with test data and application of the Modelica Thermal Model Generation Tool for a room with radiant heating and for the cooling of an aircraft cockpit are presented in this paper.

*Keywords: Thermal Model, VEPZO, Airflow Simulation, View Factor Calculation, Long-wave Radiant Heat Exchange, LowRad*

## 1 Introduction

A number of codes for thermal simulation (e.g. Indoor Climate Library [1], Buildings Library [2]) have emerged in Modelica. These models are set up in a way to allow the user a comfortable parameterization with a moderate number of models. The resolution of these models is on room level. A

typical model would consist of six rectangular enclosures, a perfectly mixed air volume and a radiation node estimating the view factors in a simplified way. Connecting a number of such basic elements and modelling an airflow network between rooms (e.g. the Multizone model of Buildings Library [3]) yields a building. To refine the airflow and temperature distribution within a room, zonal models have been implemented in Modelica ([1; 4]). The manual setup of these models is easy when only rectangular spaces are considered. Simple non-rectangular spaces with a low number of inclined surfaces can still be set up manually, too. However, the manual setup of a thermal model for more complex geometries becomes increasingly time consuming and error prone with increasing “non-rectangularity” of the geometry as surfaces and zones require a one-by-one parameterization of area, volume and location. Furthermore, the simplified radiation approach distributing radiation proportionally on surfaces (e.g. described in [5]) is only validated for building applications where typically temperature differences between surfaces are relatively small. In other configurations, the simplified approach may result in high errors of surface temperatures due to wrong estimation of view factors, which can further cause error in energy balance and estimation of comfort level.

One of the purposes of creating the Modelica Thermal Model Generation Tool is to allow estimating the impact of the location of a very hot device or the development of local radiant or convective heating strategies.

To achieve this goal, the Modelica Thermal Model Generation Tool combines two Modelica codes presented at the Modelica Conference 2012. The VEPZO model [6] computes the airflow and temperature distribution in space. Up to now, it has only been used on rectangular geometries. For non-rectangular spaces, the geometry was manually approximated by rectangular elements. The Modelica Long-wave Radiation View Factor Model [7] allows

for view factor computation based on actual geometries and creates a more detailed radiation node model. The long-wave radiation view factor model presented in Modelica Conference 2012, was not considering the obstruction check for obstructed views.

## 2 Method

This section outlines the steps of the Modelica Thermal Model Generation Tool and used models.

### 2.1 Modelica Thermal Model Generation Tool

The Modelica Thermal Model Generation Tool (MThMGT) is a pre-processing tool developed in C++ language. It translates a CAD model exported into the .stl format to Modelica code that can be simulated in the Modelica simulation environment. The .stl format describes the geometry by a series of triangles and their normals. When opening the MThMGT GUI (Figure 1), the user selects the input .stl-file and determines a grid for the subdivision of the geometry into zones. The user can add heat sources and ventilation openings in the GUI.

Based on the user-defined grid, the MThMGT distributes nodes and checks for each node whether it is within or outside the geometry. Furthermore, it checks whether two adjacent nodes are separated by a wall indicating that they belong to two different domains (i.e. room1 and room2). The nodes within one domain form the edges of the zones. The “classical” rectangular zone is thus determined by eight nodes. Zones adjacent to the geometry are defined by less than eight nodes as some nodes are outside the domain. For these zones, dedicated rules are applied approximating zone geometry and creating wall facets that approximate the actual geometry. Each zone is given a unique name to be identified for its connections to walls, heat sources, convection and radiation models and ventilation openings. To enable the user to assess the created thermal model, the geometry of created zones and wall facets is saved as .stl file in dedicated repositories. Figure 2 shows an example for the distribution of zones in geometry.

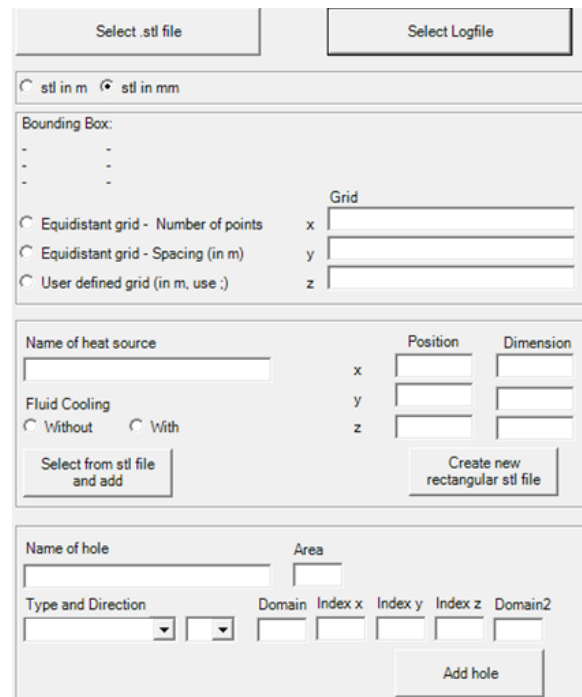

Figure 1: GUI of the MThMGT - Zonal Part

Figure 2: Example for created zonal grid

View factor computation settings are entered in the second part of the GUI of MThMGT (Figure 3). First, the user needs to state whether view factors shall be computed and what kind the geometry is of. Unobstructed view means all the surfaces in one domain have complete view of each other if they are not in the same plane. If there is any obstruction in the view of one surface to another surface, the user must select computation method for obstructed views. Similarly, if the surface is self obstructed, for example a surface is shaped as an alphabate ‘S’, the user must select the computation method for self-obstructed views. The aim of these selection possibilities is to obtain a quicker computation by avoiding unnecessary obstruction checks.

**Figure 3: GUI of the MThMGT - Radiation Part**

Accuracy of view factor computation is directly proportional to the mesh quality of a surface. Therefore, mesh refinement is required. For this, the user can define a limiting area and a limiting length of facet edges for refined triangles. This ensures that all facets are refined below this threshold. Figure 4 shows a refined mesh of the geometry shown in Figure 2.

**Figure 4: Refined meshing of created geometry for view factor computation.**

After computation of zonal grid and view factors, the MThMGT does all the appropriate connections between the zonal model, the radiation model, the convection models and the wall models. It includes heat sources and ventilation openings to the model and connects them with the appropriate zone and radiation node. The MThMGT writes all the model descriptions and connections into a Modelica file (.mo file) which can be further used in a Modelica environment for thermal simulation.

## 2.2 VEPZO zonal airflow model

The two main components of the VEPZO model are a zone model and a flow model (Figure 5). The zone (cube) and the flow (grey rectangle) models are connected by ports to form a room. These ports allow the exchange of relevant information between the flow and the zone model. The flow models have two ports to connect adjacent zones. Each zone has six ports, one for each boundary. A boolean parameter is assigned to each port to make the distinction whether the port is connected to a flow model or whether there is no flow because the zone is adjacent to a room boundary surface. Furthermore, each zone has a heat port (red square) allowing heat exchanges with models of other components like heat sources or walls.

With the MThMGT, these connection parameters are automatically set and ports are automatically connected to the respective models.

**Figure 5: Zonal model in x-z direction (y not shown); cubes: zones; grey rectangles: flows; rhombs: airflow ports; red solid squares: heat ports.**

The main task of the zone model is to compute mass and energy balances and air properties (density, enthalpy, pressure, temperature, etc) using air models of Modelica.Media.

$$\frac{\partial \rho_i}{\partial t} = \frac{\sum_j \dot{m}_{i,j} + \sum_{\text{sources}} \dot{m}_{\text{source},i}}{V_i} \quad (1)$$

$$V_i \cdot \rho_i \cdot \frac{\partial h_i}{\partial t} = \sum_j \dot{m}_{i,j} \cdot h_{i/j} + \sum_{\text{sources}} \dot{m}_{\text{source}} \cdot h_{i/\text{source}} + \sum_{\text{heatflows}} \dot{Q} \quad (2)$$

Where pressure is constant,  $V$  is the volume,  $\rho$  is the density,  $h$  is the enthalpy,  $m$  are entering and leaving airflows, and  $Q$  are heat flows in the zone.

The main task of the flow model is to compute the airflow rate between two adjacent zones. For this, forces resulting from pressure, momentum and height difference and losses are summed yielding the acceleration of the airflow in the flow paths. A detailed set of equations for the flow path can be found in [6].

### 2.3 Long-wave Radiant Heat Exchange Model: LowRad

The radiant heat exchange of a surface depends on the temperature  $T$ , the reflectivity  $\rho$ , the emissivity/absorptivity  $\varepsilon$  and for transparent surfaces the transmissivity  $\tau$ .

For an opaque surface  $i$  the incoming ( $Q_{i,\text{in}}$ ) and leaving ( $Q_{i,\text{out}}$ ) radiant heat flows are computed by:

$$Q_{i,\text{out}} = A_i \cdot \varepsilon_i \cdot \sigma \cdot T_i^4 + \rho_i \cdot Q_{i,\text{in}} \quad (3)$$

$$Q_{i,\text{in}} = \sum_j F_{i-j} \cdot Q_{j,\text{out}} \quad (4)$$

with  $\sigma$ : Boltzmann number ( $5.67 \cdot 10^{-8} \text{ W/m}^2\text{K}^4$ ),  $F_{i-j}$ : view factor of surface  $j$  to  $i$ .

Determination of the long-wave radiant heat exchange between surfaces requires the view factor matrix  $F_{i-j}$ . There are several analytical solutions available to calculate view factors for simple and known configurations. Many building simulation programs estimate the view factors in a simplified way, especially when complex geometries are involved. The simplified approach may result in high errors of surface temperatures, which can further cause error in energy balance. Hence it is important to determine accurate view factors. The purpose of creating this model is to calculate view factors between complex geometries for unobstructed, obstructed and self-obstructed views.

#### 2.3.1 View factor matrix integral

To assess the radiative exchange between non-obstructed surfaces, the corresponding view factors

between the surfaces need to be computed. View factors between two surfaces are dependent on the geometry of the surfaces and their orientation. The view factor can be interpreted as the fraction of diffusive radiant heat exchange between surface  $i$  and surface  $j$ . The view factor between two surfaces is obtained from the integral over the view factors between the infinitesimal surface elements  $dA_i$  and  $dA_j$  (equation (5) and Figure 6):

$$F_{ij} = \frac{1}{A_i} \int_{A_i} \int_{A_j} \frac{\cos \theta_i \cdot \cos \theta_j}{\pi \cdot r^2} dA_i dA_j \quad (5)$$

where  $r$  is the distance between the centres.

**Figure 6: View factor between two surfaces i & j**

It is sufficient to compute the upper triangle of the view factor matrix. The lower triangle can be constructed by the following relationship:

$$A_i \cdot F_{ij} = A_j \cdot F_{ji} \quad (6)$$

#### 2.3.2 View factor matrix computation

The input for the computation of the view factor between two surfaces  $i$  and  $j$  is their triangulation in the .stl format. The MThMGT reads vertices and the normal vector of each triangular facet. The model calculates the centre and area of each triangle, the distance between each triangle and all the other triangles and similarly directional cosines for each triangle pair. For this, the discretization of equation (5) is used:

$$F_{ij} = \frac{1}{A_i} \sum \sum \frac{\cos \theta_i \cdot \cos \theta_j}{\pi \cdot r^2} \cdot dA_i dA_j \quad (7)$$

Required angles are determined by using following equations:

$$\cos\theta_i = \frac{l_i(x_j - x_i) + m_i(y_j - y_i) + n_i(z_j - z_i)}{r} \quad (8)$$

$$\cos\theta_j = \frac{l_j(x_i - x_j) + m_j(y_i - y_j) + n_j(z_i - z_j)}{r} \quad (9)$$

with  $l, m, n$ : directional components of the normals of  $dA_i, dA_j$

$x, y, z$ : coordinates of the centers of the surface elements.

Summing this discretized integral over all triangles forming the two surfaces yields the view factor between these two surfaces. Once the view factor  $F_{ij}$  from surface  $i$  to surface  $j$  is known, the reciprocal view factor from surface  $j$  to  $i$   $F_{ji}$  can be calculated from equation (6).

### 2.3.3 Obstruction check

To check whether two surface elements are obstructed by a third element, the plane of eventual obstruction needs to be set up.

**Figure 7: Obstructed view factor between surface i and surface j**

The equation of plane is given by

$$A \cdot x + B \cdot y + C \cdot z + D = 0 \quad (10)$$

$$D = -(A \cdot x_{ob} + B \cdot y_{ob} + C \cdot z_{ob}) \quad (11)$$

Where  $x_{ob}$ ,  $y_{ob}$  and  $z_{ob}$  are the vertices of the obstructing triangular facet (in this case only one facet is obstructing the view). The equation of the line connecting centers of facets on surface- $i$  (i.e. centers of  $ds_{1i}, ds_{2i}, ds_{3i}, ds_{4i}$ ) and surface- $j$  (i.e. centers of  $dx_{1j}, dx_{2j}, dx_{3j}$ ) checks the relative position between the line and the obstructing plane. There are three possibilities:

- The line can be parallel to the obstructing plane

- The line can belong to the obstructing plane
- The line can intersect the obstructing plane.

For this, the relative position of the obstructing surface to the line is checked:

$$m = \frac{A \cdot x + B \cdot y + C \cdot z + D}{A \cdot a + B \cdot b + C \cdot c} \quad (12)$$

$$\begin{pmatrix} a \\ b \\ c \end{pmatrix} = \begin{pmatrix} x_j - x_i \\ y_j - y_i \\ z_j - z_i \end{pmatrix} \quad (13)$$

If the plane of obstruction is between surfaces  $i$  and  $j$ , the value of  $m$  is greater than 0 and less than 1.

If the denominator of equation (12) is not zero, the point  $p$  of the intersection between the line and the plane can be found using:

$$\begin{pmatrix} x_p \\ y_p \\ z_p \end{pmatrix} = \begin{pmatrix} x_i + a \cdot m \\ y_i + b \cdot m \\ z_i + c \cdot m \end{pmatrix} \quad (14)$$

Once the point  $p$  is known, the next step is to find out using barycentric technique if the point  $p$  is inside the obstructing triangle or not. If the point  $p$  is inside the triangular facet the view factor is assumed to be zero.

### 2.3.4 Radiation node model

The radiation node model calculates long-wave radiant heat exchange between  $n$  surfaces. It contains  $n$  thermal ports, surface properties and the view factor matrix. Each port connects to the corresponding surface model. The incoming and outgoing radiations for each surface are computed using the view factor matrix, temperature at each thermal port and surface properties as per equations (3) and (4).

**Figure 8: Incident radiation on two surfaces**

Application example of radiation model with obstructed view can be seen in Figure 8. There are two surfaces in front of radiant heat emitter (Globe).

Some part of surface-1 is obstructed by surface-2. Different colors represent difference in intensity of incident radiation. Due to the lower distance from the globe to surface-2, it has a higher incident radiation than surface-1. The view factor of the globe to the obstructed part of surface-1 is zero. Hence there is no direct radiant heating of the obstructed part.

## 2.4 Walls and convection models

Convection models are used from the Modelica Standard Library. Wall models are based on a suite of thermal capacitances and thermal resistances from the Modelica Standard Library. The parameterization of these models yields the different materials that can be used.

The MThMGT exports the wall type for each domain with a “none” wall. This wall has no capacitance and no thermal resistance. In the exported code, the model type can be changed to the wall actually used in the geometry.

## 3 Coupled Model Validation

The coupled airflow, radiation and wall model generated with the MThMGT has been validated on a test bench.

### 3.1 Test Setup

**Figure 9: Experimental Setup: Box with air conditioning system**

The experimental setup is composed of a box of size 2m x 1.5m x 0.9 m connected to an air supply system and insulated with 10 cm thick Armaflex foam. The box contains two heat sources in a form of equipment simulators (EQS) (Figure 9). These are installed in a test zone in a manner to have air circulation around them. By hanging them with a thin non-metallic rod their support can be considered

to be thermally insulated. Heating foils release a uniform heat flow on all surfaces of the EQS.

Conditioned air is supplied to the simulation box with a pipe of 104 mm diameter. In order to get a well developed flow at the inlet a minimum pipe length of  $L=15 \times D_{\text{hydraulic}}$  is used. This well developed flow is also required for a high inlet velocity measurement accuracy.

**Figure 10: Sensor positions: green dots: location of air temperature sensors, red dots: location of surface temperature sensors**

Figure 10 shows the distribution of measurement locations that were used for model validation in this study. Table 1 describes four different validation test cases varying supply airflow rate and long-wave emissivity of the EQS.

**Table 1: Test Cases (TC1-4), Al: aluminium surface, B: black painted surface**

	TC1	TC2	TC3	TC4
Inlet mass flow (kg/min)	10	7.5	10	7.5
Supply Temperature (K)	283.15	283.15	283.15	283.15
Pressure (hPa)	940	940	940	940
Power EQS1 (W)	500	500	500	500
Power EQS2 (W)	500	500	500	500
Surface EQS1	Al	Al	B	B
Surface EQS2	Al	Al	Al	Al

### 3.2 Results

To validate the coupled model, simulated results of four different test cases were compared with actual test results.

Figure 11 to Figure 13 show the comparison of simulated and measured air temperatures at the top left corner (TAi\_OB), the center (TAi\_M) and the bottom right corner of the box (TAi\_UF) for TC1 and TC2. In steady-state conditions, the model predicts air temperature with less than 0.5 K deviations.

**Figure 11: Air temperature at the top left corner of the box**

**Figure 12: Air temperature at the center of the box**

**Figure 13: Air temperature at the bottom right corner of the box**

Figure 14 and Figure 15 show the comparison of simulated and measured surface temperatures of EQS1 and EQS2. In the experimental setup, surface temperature sensors are placed on each face of the EQS. For model validation, these temperatures were averaged to obtain one representative surface temperature. At steady state, the deviation of measurement and simulation is less than 5 K.

**Figure 14: Surface temperature of EQS1 for TC1 and TC2**

**Figure 15: Surface temperature of EQS2 for TC1 and TC2**

To assess model validity for changed long-wave radiation properties, EQS1 was painted black for TC3 and TC4. Figure 16 and Figure 17 show the comparison of simulated and measured surface temperatures of EQS1 and EQS2. Due to higher radiative exchange, surface temperature of EQS1 is lower than that of EQS1 in TC1 and TC2. EQS2 receives more radiation from EQS1 resulting in a higher surface temperature compared to TC1 and TC2. The accuracy of model predictions is in the range of 5 K for this setup, too.

**Figure 16: Surface temperature of EQS1 for TC3 and TC4**

**Figure 17: Surface temperature of EQS2 for TC3 and TC4**

### 3.3 Discussion

Comparison with validation test data shows that results of air temperatures show slight variations during transients but are accurate in steady state. The model predicts the surface temperature of EQS well for both transient and steady state conditions and for different emissivity. The impact of a higher radiative loss of the black EQS might have been visible even in a simplified radiation approach. However, the relatively higher surface temperature of the other

EQS, still being low emissive, would not have been correctly predicted without the computed view factor matrix finding a considerable radiative heat exchange between both EQS.

## 4 Application Examples

This section shows two application examples that have been setup using the MThMGT.

### 4.1 Radiant heating of a room

In this example the MThMGT has been used to assess the impact of radiant heating. Figure 18 shows three sides of a room with a wall heater, a table and a sitting manikin. The table is located in the center of the room. It has been subdivided into ten parts, three on the right, three on the left and four on the lower side of the desk. The impact of using these parts as radiant heating sources by applying a heating foil on them is investigated. Zoning has been done such that each heat source lies in a separate zone.

**Figure 18: MThMGT application example of building room**

Figure 19 shows the result of different parts of the manikin. The temperatures of legs and thighs are higher than other body parts because of the radiant heating from the heating foils on the inner sides of the table. The temperature of the left hand is higher than that of the right hand, as the left hand is closer and in line of the wall heater. The left part of the chest is cooler than the left arm even though being in line with the heater due to the obstruction caused by left arm.

**Figure 19: Temperatures of manikin body parts**

## 4.2 Cockpit Ventilation

In order to determine the required ventilation performance of the aircraft air conditioning system, heat loads have to be balanced with the airflow requirements in the most challenging operating conditions. Major heat sources in the aircraft cabin are passengers, electrical devices, solar radiation, indirect heating from piping and additional driving factors such as hot and humid environmental conditions on ground or at low flight level. Lightings in the cabin and IFE are also major heat sources. The MThMGT allows investigating aircraft cooling strategies.

**Figure 20: CAD and Zonal Grid of an aircraft cockpit**

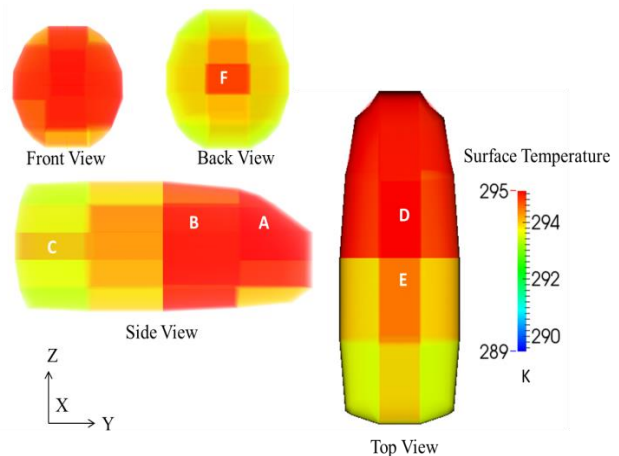

Figure 20 shows the CAD geometry of an aircraft cockpit (top). The cockpit is subdivided into 4x3x5 zones assuring that each EQS is located in a separate zone (bottom). Heat productions of EQS1, EQS2 and EQS3 are set to 2.0, 1.0 and 1.5 kW respectively.

**Figure 21: Auto-Generated Thermal Model**

Figure 21 shows the generated thermal model connected to the airflow sources and the pressure sink. There are four airflow inlets in the cockpit: two at the top and two at the bottom. The outlet is located in the center of the rear side. The user needs to define boundary conditions such as inlet airflow rate, inlet air temperature, sink air pressure and exterior temperature and to select an appropriate wall model from a wall model package.

Simulation results are exported into the Paraview visualization format for post-processing [8]. Figure 22 shows simulated wall inner surface temperatures of the cockpit. The impact of radiation from equipment simulators is reflected in results. Facets A, B and D are in close vicinity to EQS1 and EQS2. Facet C and F are influenced by EQS3. Facet E receives radiation from both EQS2 and EQS3.

**Figure 22: Wall inner surface temperatures**

Figure 23 shows simulated air node temperatures in the cockpit. EQS1, EQS2 and EQS3 are located in zones A, B and C respectively. In these zones, air temperature is predicted to be higher than in the other, empty zones.

**Figure 23: Air node temperatures**

## 5 Conclusion and Outlook

A tool to model airflow and radiative heat transfer for complex geometries in 3D space has been outlined in the presented work. The Modelica Thermal Model Generation Tool closes the gap between the CAD model and the resulting Modelica thermal model. The exported model shows to correctly predict the interaction of radiative and convective heat transfer in an experimental validation case. The possibility to model the impact of radiative heating and to assess the impact of different airflow pattern on heating and cooling has been proved for both rectangular and irregular geometries.

The disadvantage of the generated code is that it is plain text with only scarce use of the graphical programming possibilities of Modelica. Further customization or changes in the model therefore require a high level of expertise of the user both in terms of the logics of the generated model and the code of contained models.

To keep the model accessible even for less experienced users, an export script allowing the visualization of simulation results in the open source post processing software ParaView has been written. From this visualization, the user can for example assess cooling and heating strategies or find local hot or cold spots.

For the future, we intend to include a model which can calculate convective heat transfer coefficients considering local zonal airflow pattern, surface properties and its orientation. This development provides a tool to predict thermal comfort in enclosed 3D spaces. This tool will allow for better thermal modelling when considering thermal management in buildings, automobiles or aircrafts.

## Abstract

There are different options for modelling indoor and outdoor long-wave radiation exchange in thermal building models for simulations at urban scale. For improving these building models, a good trade-off between accuracy and simulation time is a major challenge. To evaluate different radiation models for thermal network building models, we compared four outdoor radiation and two indoor radiation models.

For the comparison, we set-up three test cases on a generic room and a single family dwelling and analysed surface temperatures, heat demands, and simulation times. The results favoured an outdoor radiation exchange model according to the German Guideline VDI 6007 with modified parameter calculations. It includes important simplifications that lead to short computing time while keeping a sufficient accuracy. For indoor radiation exchange modelling at constant temperatures, a linear approach significantly reduces simulation time without any major accuracy losses.

*Keywords: thermal network building model, equivalent outdoor temperature, long-wave radiation exchange, building performance simulation*

## 1 Introduction

One current challenge in the field of building simulation is the thermal simulation of entire city districts. For this task, simplified building models are an interesting approach as they require comparably low parameterization and computational efforts. A comprehensive discussion of this topic can be found in [1, 2], which summarize the state-of-the-art in dynamic building simulation. The approaches to simplify building models include thermal network models, which are based on analogies to electrical problems and have successfully been applied at urban scale [3, 4].

Thermal simulation at urban scale aims at understanding and efficiently directing energy flows between different subsystems like generation units and buildings. Of particular interest are holistic control strategies and heat storage effects, because they offer potential for improving the energy system without the need for high investment. To investigate such measures, dynamic simulations at variable time step seem more promising than static and quasi-static calculations. Nevertheless, traditional building simulation environments are often limited to an hourly time step. Thus, a growing community is developing model libraries to simulate building performance at building and urban scale using Modelica [5, 6, 7, 8], often using thermal network models to describe thermal building behaviour.

Within common thermal network models, the long-wave radiation heat fluxes on wall surfaces can be considered on different levels of detail. These heat fluxes are the result of temperature differences caused by indoor and outdoor sources such as heating systems and solar radiation. Different approaches exist for the calculation of radiative heat exchange. Some models use Stefan-Boltzmann law while others use linearized radiation equations. Thus, these models differ in the accuracy of their results as well as in computation time. So far, it has not been determined which of these models is best suited for thermal simulation at urban scale.

In this paper, we present four approaches to consider long-wave radiation exchange in building simulation. The aim is to evaluate these approaches regarding their suitability for thermal network building models and urban-scale applications by means of a balanced trade-off between physical resolution and calculation time [9].

Firstly, we present the methodology and modelling assumptions. Afterwards, we implement four models and define a benchmark test case. Finally, we discuss the simulation results and end with conclusions.

## 2 Modelling approaches

### 2.1 Building model validation

Thermal network models describe heat transfer and storage problems with a number of thermal resistances and capacitances. While highly discretized models provide high spatial resolution, low order models require less computational effort at the cost of accuracy.

Figure 1: Low order building model derived from VDI 6007

In this study, we use a building model based on the German Guideline VDI 6007 [10] as seen in Figure 1. The model divides the building mass into two capacitances representing all internal and external building elements respectively. The heat transfer through the outer wall is described by two resistances while another resistance is used to damp the adiabatic inner wall capacity. The indoor heat exchange between the walls and the air node can be calculated in different ways. While the VDI 6007 defines a combined coefficient of heat transfer, we distinguish between radiative and convective heat transfer (Figure 1). Outdoor radiation sources like solar radiation are considered via an adapted equivalent outdoor air temperature  $\vartheta_{A,eq,av}$  (in the following referred to as  $T_{eq}$ ). Substituting the outdoor air temperature with this equivalent outdoor air temperature is a way to incorporate the effects of long-wave radiation into the model.

While we kept most parts of the theory and model description given in VDI 6007, we did not follow the given analytical equations [11]. We rather took advantage of Modelica's abilities to formulate acausal equations in an object-oriented structure. We defined a sub-model for each element in Figure 1 and connected them to the circuit shown in Figure 6. Each sub-model describes either heat transfer phenomena (resistance) or storage effects (capacity)

In order to validate this thermal network model, we performed benchmark tests according to the American Standard ASHRAE 140 [12]. This standard provides a set of test cases and

corresponding results of standard building models. If deviations in the validation process exceed given limits, the standard suggests further test procedures for each test case. In this way, the standard supports the identification of sub-models with optimisation potential. The tests gave valid results for most test cases. Nevertheless, the validation process identified problems with the handling of radiation exchange. One way to address this issue would be more detailed radiation exchange models, while potential simplifications should still be considered. Otherwise, radiation and building model could be out of balance by means of level of detail and required computational costs.

We identified long-wave radiation exchange as one key part for optimization. It seems to have major influence on heat demand [13] and different modelling approaches are available. As the ASHRAE provides no test case solely for the effects of long-wave radiation heat exchange, we refined one ASHRAE in-depth test set-up to focus only on long-wave radiation.

In the following sections, we will discuss and compare different approaches for outdoor as well as indoor long-wave radiation heat exchange.

### 2.2 Outdoor long-wave radiation exchange

According to VDI 6007, the heat flux due to ambient radiation sources on the outer walls can be considered in an equivalent adapted outdoor temperature.

Figure 2 shows typical influences that need to be considered in the adapted outdoor temperature. Radiation can be divided into short-wave and long-wave. In contrast to short-wave radiation, measurement data of long-wave radiation sources are rarely available. Furthermore, long-wave radiation has to be subdivided into atmospheric, ambient and partly reflected ground radiation. Thus, empirical methods are used to consider the long-wave heat flow as a function of outdoor temperature and cloud coverage [14, 15, 2].

Figure 2: Heat flows on the outer wall

According to Figure 2 a heat balance of the wall consists of:

$$q_{cond} = q_{short-wave} + q_{long-wave} + q_{conv} \quad (1)$$

Starting from this heat balance it is possible to implement models with different levels of simplifications (see Figure 3).

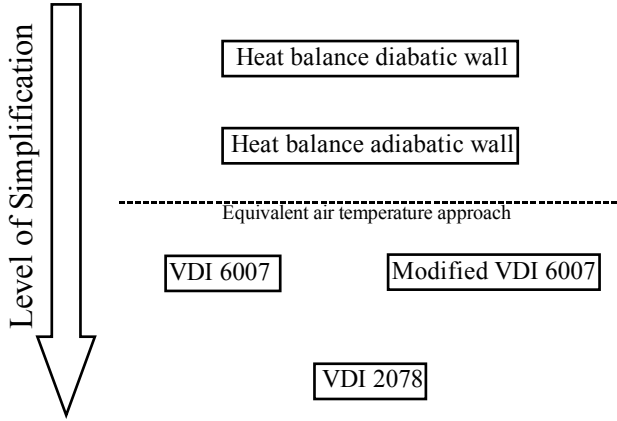

Figure 3: Schematic diagram of investigated models and their level of simplification

As a first simplification the outside wall can be considered as adiabatic, which leads to  $q_{cond} = 0$ . In the following subsections we describe four ways to model long-wave radiation heat exchange. The meaning of the variables can be found in the nomenclature.

### 2.2.1 Heat Balance

The three occurring heat flows can be written as:

$$q_{conv} = \alpha_{conv} \cdot (T_{air} - T_{wall}) \quad (2a)$$

$$q_{long-wave} = \sigma \cdot \epsilon_{wall} \cdot (\varphi_{atm} \cdot (T_{atm}^4 - T_{wall}^4) + \varphi_{earth} \cdot (T_{earth}^4 - T_{wall}^4) + \varphi_{amb} \cdot (T_{air}^4 - T_{wall}^4)) \quad (2b)$$

$$q_{short-wave} = a_{abs} \cdot I_{sol} \quad (2c)$$

$\varphi_i$  is a view factor between the wall and considered long-wave radiation source. The temperature of extra-terrestrial sources, also called sky temperature, can be calculated as a function of long-wave radiation heat flux. Furthermore, the earth temperature can be regarded as equivalent to the outdoor air temperature [16, 17]:

$$T_{atm} = \left( \frac{E_{atm}}{\sigma} \right)^{0,25} \quad (3a)$$

$$T_{earth} = T_{air} \quad (3b)$$

Inserting Equations 2 a-c and 3a/b in Equation 1 provides the heat balance of the adiabatic outside wall. This heat balance can be iteratively solved for  $T_{wall}$ . Without any further simplifications, this Heat Balance method provides a relatively detailed model.

### 2.2.2 Equivalent air temperature according to VDI 6007

A widely used simplification is to describe the occurring heat flows with one equivalent heat flux [10, 18, 19]. Introducing a combined radiative and convective coefficient of heat transfer and an equivalent temperature leads to:

$$\alpha_{comb} \cdot (T_{eq} - T_{wall}) = q_{short-wave} + q_{long-wave} + q_{conv} \quad (4)$$

Expressing the equivalent temperature according to VDI 6007 requires further assumptions. The long-wave radiation heat exchange is linearized using  $T_{atm}$  and  $T_{earth}$ , the wall temperature is set equal to the outdoor air temperature and  $T_{atm}$  and  $T_{earth}$  are calculated from long-wave radiation heat flows.

$$T_{atm} = \left( \frac{E_{atm}}{\epsilon_{earth} \cdot \sigma} \right)^{0,25} \quad (5a)$$

$$T_{earth} = \left( \frac{E_{earth}}{\epsilon_{earth} \cdot \sigma} \right)^{0,25} \quad (5b)$$

$$\alpha_{rad} = \frac{T_{atm}^4 - T_{earth}^4}{(T_{atm} - T_{earth})} \cdot \sigma \cdot \epsilon_{wall} \quad (5c)$$

Transforming the equation (4) to  $T_{eq}$  and apply the listed assumptions, the equivalent temperature can be solved as follows:

$$T_{eq} = T_{air} + \frac{\alpha_{rad}}{\alpha_{comb}} \cdot ((T_{atm} - T_{air}) \cdot \varphi_{atm} + (T_{earth} - T_{air}) \cdot \varphi_{earth}) + \frac{q_{short-wave}}{\alpha_{comb}} \quad (6)$$

### 2.2.3 Modified equivalent air temperature based on VDI 6007

Equation 6 implies a constant combined coefficient of heat transfer. As a further improvement,  $\alpha_{comb}$  is computed as the sum of constant  $\alpha_{conv}$  and a variable coefficient for long-wave radiation heat transfer  $\alpha_{rad}$ .

In addition, both  $T_{atm}$  and  $T_{earth}$  are computed by dividing them through the emissivity factor of the earth. According to [16, 17], it is more accurate to calculate the sky temperature with Equation 3a. These changes from the originally VDI 6007-model are summarized under the variant name Mod VDI 6007.

### 2.2.4 Combined outdoor temperature according to VDI 2078

The revised German Guideline VDI 2078 describes cooling load calculations and provides a combined outdoor temperature. Formally, this temperature originates from a similar approach as the VDI 6007. However, the VDI 2078-model is further simplified by neglecting any changes in sky emissivity or in the coefficient of long-wave radiation heat exchange. Sky emissivity is set to 0.74, which holds roughly

true for summer [20]. Besides, the air temperature is taken as the direct reference temperature for all calculated heat fluxes. As this model represents a further simplification, we include it in our study and compare its results to the other three models.

$$T_{eq} = T_{air} - \frac{\sigma \cdot \epsilon_{wall}}{\alpha_{comb}} \cdot ((T_{air,m})^4 + (T_{air} - T_{air,m}) \cdot 1.05) \cdot (1 - \varphi_{atm} \cdot \epsilon_{atm} - \varphi_{earth} \cdot \epsilon_{earth}) + \frac{q_{short-wave}}{\alpha_{comb}} \quad (7)$$

### 2.3 Indoor long-wave radiation exchange

The long-wave radiation heat exchange within the building is commonly modelled in two different ways. One possibility, described in the VDI 6007 guideline, suggests calculating this way of heat exchange with a constant coefficient of heat transfer between inner and outer wall. The guideline prescribes a value of 5 W/(m<sup>2</sup> K), which can also be found in [21]. It holds true for non-metallic materials with an emissivity factor of 0.8 and a mean temperature of 26.85°C. This method does not take into account the temperature dependency of long-wave radiation heat exchange as formulated in the Stefan-Boltzmann law.

Alternatively, a heat balance between inner wall, outer wall, indoor radiation sources and transmitted solar radiation can be formed.

## 3 Implementation

For this study, we use the Modelica Standard Library and self-developed building model libraries. An overview of these libraries is given in [6, 22].

As all radiation heat exchange models described in Section 2 derive from a similar theoretical approach, we are able to define a partial model as a general base class (Figure 4).

Figure 4: UML diagram of equivalent air temperature base class

The four different long-wave radiation exchange models all extend from this base class. This gives us the advantage to define a replaceable block for long-wave radiation heat transfer (1) connected to our building physics model (2) which can then be set to

use one of the four radiation models (Figure 5). The building model is connected via heat ports to the long-wave radiation heat transfer (a). Both are connected with a weather model, which provides solar radiation (b), outdoor air temperature, sky and terrestrial long-wave radiation (c). Furthermore, the building model needs additional information about infiltration rates (d), as well as about convective (e) and radiative (f) inner loads via heat ports.

Figure 5: Implementation in Dymola

Taking advantage of separated definitions of convective and radiative heat transfer (see Section 1), we can easily change the definition of long-wave radiation heat exchange (see Figure 6).

Figure 6: Zone model in Dymola

In the context of city district simulations, the object-oriented approach of Modelica is an important

advantage. It allows a fast and easy use of the same model in several instances while adapting the sub-models to the requirements of each instance.

A further advantage besides variable time step and object-orientation supported by Modelica in this context is acausal modelling. Energy supply systems at urban scale are relatively complex and flow directions for energy and mass flows are usually unknown.

## 4 Test case and results

### 4.1 Test case

To figure out the differences between the models and identify the most promising approach for our building model, we developed three test cases. Test Case 1 and Test Case 2 are based on the “Case 220: In-Depth Series Base Case” from ASHRAE 140. As most ASHRAE 140 in-depth tests, it is based on a single room consisting of five light-weight outer walls only. We simulated 1<sup>st</sup> July of the typical meteorological year (TMY) provided with the standard [12]. Before and after the simulated day all initial temperatures are held constant. For Test Case 1 the outside wall is only subject to outdoor air temperature and long-wave radiation. Convection and absorption of short-wave radiation are not considered. Thus Test Case 1 uses outdoor air temperature and long-wave radiation from the atmosphere and the earth as input-data. Test Case 2 differs in the number of heat transfer mechanisms which affect the building envelope. Convection and absorption of short-wave radiation are additionally taken into account. Further inputs are thus solar radiation on tilted surfaces and combined as well as convective coefficients of heat transfer (set to 28.5 W/(m<sup>2</sup> K) and 24.67 W/(m<sup>2</sup> K) for walls, and 16.37 W/(m<sup>2</sup> K) for windows respectively). Only one day is simulated as well, all temperatures are held constant before and after that day. Other parameters of Test Cases 1 and 2 are listed in Table 1.

Table 1: Boundary conditions of Test Case 1 and 2

PARAMETER	VALUE
Infiltration	0 m <sup>3</sup> /h = const.
Internal gains	0 W = const.
Temperature of floor coupling	T <sub>air</sub>
$\alpha_{\text{abs}}$	0.6
$\epsilon_{\text{wall}}$	0.90
mech. equipment	none

The purpose of Test Case 3 is to emphasize on the inside long-wave radiation heat exchange, heat

demand and simulation time. Since the simplified building model represents all outer and inner walls by one capacitance per class (see Section 2.1), radiation exchange can only occur if elements of both classes exist. We thus set up a test case with outer as well as inner walls. Test Case 3 is based on a two storey single-family dwelling with a living area of 150 m<sup>2</sup>. The building has a high thermal mass and is well insulated according to German Energy Savings Ordinance 2009. A full year is simulated. Calculation of the equivalent air temperature is performed with convective and long-wave radiation heat transfer as well as short-wave absorption. Combined and convective coefficients of heat transfer are set to 25 W/(m<sup>2</sup> K) and 20 W/(m<sup>2</sup> K) respectively. The boundary conditions for this case can be found in Table 2.

Table 2: Boundary conditions of Test Case 3

PARAMETER	VALUE
Infiltration	0 m <sup>3</sup> /h = const.
Internal gains	0 W = const.
Temperature of floor coupling	10.36°C = const.
$\alpha_{\text{abs}}$	0.38
$\epsilon_{\text{wall}}$	0.90
mech. equipment	ideal heater
Thermostat strategy	22°C (6h – 20h) 17°C (20h – 6h)

All simulations are performed on a computer with following technical data (see Table 3).

Table 3: Data of used equipment

CHARACTERISTIC	VALUE
Operating system	Windows 7
Number of processors	4
Clock speed	2.67 GHz
Working memory	4 GB

To quantify differences between the models, a root-mean-square deviation (RMSD) is used. When comparing more than two models it is appropriate to form the RMSD between the minimum and the maximum of each hour. In this way a range within which the temperatures lie is calculated (RMSD-R).

### 4.2 Limitations

The major limitations in the presented work are:

- Subject of this analysis are only single-zone buildings with specific characteristics
- All models are based on assumptions; the results are compared between each other but not to measurements.

- Empirical equations are used to calculate long-wave radiation as a function of outdoor air temperature. Thus, all models are dependent either directly or indirectly on outdoor air temperature.
- Heat balances for the models relate to slightly different locations (wall surface or nearby the surface) and cannot be harmonized.
- Convective heat transfer  $\alpha_{\text{conv}}$  is regarded constant. In reality, it may vary over time depending on wind speed and direction.
- Our presented analysis is limited to single days and overall yearly values.

### 4.3 Outdoor long-wave radiation exchange

To understand the differences between the models, we investigated the surface temperatures on the building envelope as direct model outputs. The results of Test Case 1 with long-wave radiation load can be obtained in Figure 7. While the temperature of the VDI 6007-model holds the highest values, the model of guideline VDI 2078 holds the lowest. The RMSD between these two models is 11.24 K. The high temperatures of the VDI 6007-model close to the outdoor air temperature are striking. In other investigations a rise above the outdoor air temperature was detected, which contradicts observation [23]. The Mod VDI 6007-model has a clearly lower course and converges to the most detailed Heat Balance-model. It is apparent that Mod VDI 6007 differs the most at high temperatures from Heat Balance. The RMSD between these two models is 0.54 K in contrast to 2.56 K for VDI 6007 and Heat Balance.

Figure 7: Equivalent outdoor temperature on July, 1. of TMY; long-wave load

The comparably low temperatures of VDI 2078 can be explained by the handling of sky emissivity. The

emissivity is assumed to be constant, which cannot be guaranteed for the investigated day. Sky conditions or reflection of long-wave radiation are not taken into account. Furthermore, the long-wave radiation heat transfer coefficient is not calculated dependent on ambient conditions.

Modifications in Mod VDI 6007 compared to VDI 6007 primarily concern long-wave radiation exchange. They cause a shift in the results towards the Heat Balance-model. Both models, Mod VDI 6007 and Heat Balance, calculate the sky temperature in the same way. Small differences at high temperatures can be justified as the Mod VDI 6007-model does not take a temperature depending emission of the wall into account.

Test Case 2 is a more realistic test case as it takes convection and short-wave radiation into account (see Figure 8). The aim is to analyse the impact of long-wave radiation under real conditions. As expected, the differences between the models decrease due to the new influences. Mainly responsible for this is convective heat transfer. This heat flux is calculated with a constant coefficient of 24.67 W/(m<sup>2</sup> K) for walls and 16.37 W/(m<sup>2</sup> K) for windows in all models, hence it is about 3-6 times higher than radiative heat transfer. However, the VDI 6007 and the VDI 2078 still represent the extremes. The RMSD between these two models decreases to 2.22 K. Especially the extreme rise of VDI 2078 in contrast to the first test case is striking. The difference in the temperature after 24 h amounts to over 10 K. On the one hand this shows the overestimation of long-wave radiation heat transfer of VDI 2078. On the other hand it displays the effect of convective heat transfer. Comparing Mod VDI 6007 and the Heat Balance, a difference is hardly recognizable (RMSD: 0.1 K). All adapted temperatures rise over the ambient air temperature during the day, resulting from the short-wave radiation absorption.

Regarding the given test cases, the results justify the implemented simplifications in the VDI 6007 and Mod VDI 6007-models. Only the VDI 2078 shows major differences to the most complex Heat Balance-model.

As expected, the convective heat transfer smoothes the equivalent temperatures of all models in Test Case 2.

Figure 8: Equivalent outdoor temperature on July 1 of TMY; long-wave, short-wave and convective load

An overestimation of long-wave radiation heat exchange of VDI 2078 can be clearly observed. The rise over air temperature during the day in all models is caused by short-wave radiation absorption of the wall. In both test cases the strong dependency on the air temperature can be monitored.

In conclusion the Mod VDI 6007 model keeps the best accuracy compared to the complex Heat Balance-model while including important simplifications that lead to shorter computing times (see Figure 9).

#### 4.4 Indoor long-wave radiation exchange

Besides the outdoor long-wave radiation heat exchange, different options exist to model indoor radiation exchange. In our analysis, we focus on heat demand and simulation time.

Figure 9 shows the CPU-time for a one-year simulation of Test Case 3. We simulated each equivalent temperature model with both explicit heat balance following the Stefan-Boltzmann law and a linearized approach. The CPU-time decreases using the linearized approach for indoor radiation. The percentages of savings in simulation time for simplified outdoor models are particularly remarkable. For the VDI 6007-model the simulation time is 52.16% shorter compared to the detailed indoor heat balance. The differences in simulation time result from the removal of the heat balances calculated with the Stefan-Boltzmann law. These heat balances contain a dependency on  $T^4$ , which is solved iteratively. This is also the reason for the massive increase of needed time using Heat Balance-model for the outdoor heat exchange.

Figure 9: Comparison of linear radiation model and Stefan-Boltzmann law for indoor radiation exchange

As we control the indoor temperatures on a level between 17°C and 22°C, the chosen coefficient of radiative heat transfer is justified (see Section 2.3). Hence, the different modelling approaches lead to no major differences in the simulated heat demand. Comparing the indoor models to each other the deviation over one year is below 2.1%. This suggests using a linear approach for indoor radiation when keeping the indoor temperature on a controlled level is a valid simplification. Nevertheless, it is important to choose a corresponding coefficient of radiative heat transfer.

## 5 Conclusion

There are different options for modelling the indoor and outdoor long-wave radiation exchange in thermal building models for simulations at urban-scale. For improving these building models, a good trade-off between accuracy and simulation time is a major challenge. The main differences of common radiation modelling assumptions concern the impact of outdoor radiation sources and linearizing the Stefan-Boltzmann law.

To evaluate different radiation models for thermal network building models, we compared four adapted outdoor air temperature models. In addition, we investigated the handling of indoor radiation exchange with the Stefan-Boltzmann law and a linear approach.

For the comparison, we set-up three test cases on a generic room and a single family dwelling and analysed surface temperatures, heat demands and simulation times. We varied the number of radiation sources between the test cases to observe radiation heat exchange under generic and real conditions.

Modelica proved to be a promising modelling language for urban-scale building simulations. We identified three major prerequisites and advantages:

- Allowing solvers with variable time steps
- Use of object-oriented modelling approaches
- Use of acausal modelling approaches

The results of the test cases show promising potential for an outdoor radiation exchange model based on a modified approach from German guideline VDI 6007. It includes important simplifications that lead to short computing time while keeping a sufficient accuracy. For indoor radiation exchange modelling at constant temperatures, a linear approach significantly reduces simulation time without major losses in accuracy. An additional comparison with measurement data could further help to validate this suggested approach.

## Abstract

Electric machine theory and electric machine simulations models are often limited to three phases. Up to the Modelica Standard Library (MSL) version 3.2 the provided machine models were limited to three phases. Particularly for large industrial drives and for redundancy reasons in electric vehicles and aircrafts multi phase electric machines are demanded. In the MSL 3.2.1 an extension of the existing FundamentalWave library has been performed to cope with phase numbers greater than or equal to three. The developed machine models are fully incorporating the multi phase electric, magnetic, rotational and thermal domain. In this publication the theoretical background of the machines models, Modelica implementation details, the parametrization of the models and simulation examples are presented.

*Keywords: Modelica Standard Library, multi phase, electric machine models, induction machine, synchronous machine, synchronous reluctance machine*

## 1 Introduction

Three phase induction, synchronous and synchronous reluctance machines are state of the art solutions for industrial applications, traction drives in electric vehicles, railways, trams, and underground trains, as well as air craft motors and generators. If a full leg of the supplying three phase converter fails, the machine cannot be operated any more, once stopped. In particular, the higher ambient temperatures of traction machines may cause the power electronics to fail. In order to overcome machine outage due to a single converter leg failure, phase numbers greater than three may be used for electric machines and power electronics. In the following multi phase will indicate phase numbers greater than three. If it is referred to only three phases, this will be indicated explicitly.

Multi phase drives consist of the multi phase machine including an inverter with power electronics plus control. A phase number greater than three thus requires a higher number of power electronic switches, such as IGBTs or MOSFETs, etc. The higher phase numbers, however, increase

cost and add complexity to the drive structure.

However, phase numbers equal to  $2^n$  with integer  $n$  are excluded from the actual implementation. The reason for excluding these phase numbers is that for example four or eight phase machines have to be handled differently since two phase are separated by  $\pi/2$ , not  $\pi$ . In general, two different philosophies of multi phase drives exist:

First, the number of phases is divisible by two. In industry, typically, six phase machines are used to overcome maximum power limitations of power electronics supplying high power machines in the Megawatt range [1]. In this case maximum power of power electronics is doubled by using two three phase converters supplying a six phase machine. Usually, the phase winding orientations of the two three phase are spatially shifted by  $30^\circ$  in order to additionally reduce the magnitudes of space harmonics caused by the winding magneto motive force (MMF) and to reduce the torque ripple of the machine, respectively. The implementation of a six phase winding does not significantly increase cost of the electric machine compared with a three phase machine with the same power. Solely the additional winding ends have to be conducted to the terminal box. For six phase drives, the cost of power electronics increases due the double number of power electronic switches for the additional legs. For doubling the power of industrial drives the double cost of power electronics is in line with doubling the power. However, for traction machines six or nine phase machines are used for redundancy reasons [2, 3]. In this case several state of the art three phase converters can be used. The redundancy concept is then realized with standard components which is cheaper than designing the individual legs of the inverter. Yet, several three phase inverters of smaller power rating are usually more expensive than a three phase inverter of the same total power. Due to the multiple three phase inverters installation space increases, too. Yet, state of the art control for three phase drives can be adapted with relatively low effort due to modularly using three phase converters.

Second, the number of phases is not divisible by two. In this case mostly five (or seven) phase drives are used [4–6]. The drawback over a six phase inverter is that the modularity of the power electronics design is lower and thus cost may be higher and more design space may be required.

For the sake of completeness one more redundancy concept will be discussed here, even though it is not related with multi phase electric machines. Redundant drives with three phase machines may use modified topologies which either use an additional leg or additional switches to operate the machine in case of a failure. These topologies have the capability to be reconfigured when a failure occurs [7, 8]. Depending on the actual topology even the full power rating may be provided to the electric machine.

For controlling multi phase electric drives it is advantageous to control current components which represent the fundamental wave MMF and magnetic voltage, respectively [9]. The pulse width modulation scheme for multi phase converters with phase numbers not divisible by three has to be adapted so that a symmetrical supply can be achieved. A technical paper dealing in more detail with analysis of the multi phase drive control is also submitted to the Modelica 2014 conference and will be cited properly, in case it gets accepted.

In Modelica the first three phase electric machine models have been introduced with the MSL 2.1 in 2004 [10, 11]. An alternative implementation with magnetic fundamental wave phasors was introduced in MSL 3.2 in 2010 [12]. Since then in these models copper loss, (eddy current) core loss, friction loss, stray load loss, PM loss and brush loss are taken into account. Multi phase electric machine models have already been published decades ago [13, 14]. Yet, in most computer simulations tools there are currently only three phase machine models available. However, in the MSL 3.2.1 version of the package `Modelica.Magnetic.FundamentalWave` new multi phase electric machine models are introduced. In general, arbitrary phase numbers for stator (and rotor) windings may be used – excluding phase numbers equal to  $2^n$  with integer  $n$ . This article provides the theoretical background, details about the implementation, parametrization schemes and some examples.

## 2 Fundamental Wave Theory

Multi phase electric machine theory often relies on phasor transformations of currents, voltages and magnetic fluxes [15, 16]. A typical transformation is the symmetrical components of the instantaneous values. In case of fully symmetrical supply the machine equations based on the symmetrical components of instantaneous components can be simplified extensively.

The FundamentalWave machine models only consider fundamental wave effects so there is also a complex phasor representation of the fundamental wave of the magnetic flux and magnetic potential (difference), respectively. The connector definition of the FundamentalWave library shows:

```
connector MagneticPort
  "Complex magnetic port"
  Modelica.SIunits.
    ComplexMagneticPotentialDifference V_m
    "Complex magnetic potential difference";
  flow Modelica.SIunits.
    ComplexMagneticFlux Phi
```

```
"Complex magnetic flux";
end MagneticPort;
```

Please note, that the potential and flow variable of the connector represent instantaneous quantities  $\underline{\Phi} = \Phi_{re} + j\Phi_{im}$  and  $\underline{V}_m = V_{m,re} + jV_{m,im}$ . The complex magnetic quantities represent a spatial distribution of magnetic flux and magnetic potential (difference):

$$\begin{aligned}\Phi(\varphi) &= \text{Re}[(\Phi_{re} + j\Phi_{im})e^{-j\varphi}] \\ &= \Phi_{re} \cos(\varphi) + \Phi_{im} \sin(\varphi) \\ V_m(\varphi) &= \text{Re}[(V_{m,re} + jV_{m,im})e^{-j\varphi}] \\ &= V_{m,re} \cos(\varphi) + V_{m,im} \sin(\varphi)\end{aligned}$$

The complex potential (difference)  $\underline{V}_m$  introduced in the connector definition represents the total magnetic potential (difference) of all poles. This quantity can, thus, also be seen as the complex magnetic potential difference of an equivalent two pole machine. Physical interpretations of the complex magnetic phasors are presented and discussed in [12].

Voltages and currents are instantaneous quantities, so arbitrary waveforms and operating conditions are covered. Therefore, the machines can also be supplied with asymmetric voltages or currents. It is yet assumed that only fundamental wave effects due to these asymmetries are considered. Supply voltage or current imbalance give rise to time transient magnitudes of the magnetic flux and magnetic potential (difference). Each of the spatial field distributions can be interpreted as a forward and backward traveling fundamental wave component. Those effect of the two waves is correctly taken in account by the proposed approach.

Particular supply imbalances and certain asymmetries may cause magnetic flux and magnetic potential (difference) phasors which are not related with the fundamental wave. Those higher harmonic waves are not covered by the FundamentalWave library. It is therefore the user's responsibility to consider these model limitations – with particular focus on the supply conditions.

Any higher harmonic wave effects are also not taken into account by the FundamentalWave library. In case of higher harmonic waves an alternative implementation has to be considered as presented in [17]. The impact of rotor saliency on the fundamental wave components of magnetic flux and magnetic potential (difference) is, however, considered in the presented implementation.

Concentrated windings and fractional slot windings, respectively, are very common in PM synchronous machines due to better field weakening capabilities, higher pole numbers and higher power density. Such fractional slot windings can be considered in the FundamentalWave library, as long as the main power exchanging harmonic component is interpreted as fundamental wave. All higher harmonic waves cause by fractional slot windings are not explicitly considered, but the total effect of those higher harmonics can be taken into account by the total leakage inductance of the stator winding.

Figure 1: Coil of an equivalent two pole machine with orientation; complex magnetic potential (difference) phasors  $\underline{V}_m$ ; complex magnetic flux phasor  $\underline{\Phi}$

## 3 Electromagnetic Coupling

### 3.1 Single Phase Electromagnetic Coupling

The coupling of fundamental wave magnetic flux and magnetic potential (difference) interacting with instantaneous voltages and currents is elementary modeled in the electro magnetic coupling models `SinglePhaseElectroMagneticConverter`. Figure 1 shows the magnetic phasors and a winding of an equivalent two pole machine. In this case one magnetic pole covers a spatial angle equal to  $\pi$ . The displayed coil is skewed and coil span is smaller than  $\pi$ . The coil can actually also be seen as a distributed winding. Skewing and distributed windings with respect to the fundamental wave are considered by the effective number of turns, represented by the parameter `effectiveTurns`. The effective number of turns of a real machine is determined by the real number of turns, multiplied by the skewing factor and the chording factor. A more detail investigation on common windings and the determination of winding factors is published in [10, 18]. A current through the investigated windings gives rise to magnetic potential (difference) distribution which magnitude is equal effective number of turns times the current. The peak of accessory sinusoidal magnetic potential (difference) caused by the current is in line with the orientation of the winding axis.

In an electric machine several windings of stator and rotor windings and permanent magnets contribute the total magnetic potential difference – depending on the type of machine. In the electromagnetic coupling model two physical laws are implemented, i.e., Ampere's law and the induction law.

### 3.2 Ampere's Law

Ampere's law states that the total exciting magneto motive force is equal to the magnetic potential difference. For the investigated single phase winding it is useful to define the complex number of turns:

```
final parameter Complex
N=effectiveTurns*Modelica.ComplexMath.exp(
```

```
Complex(0, orientation))
"Complex number of turns";
```

This complex quantity has the magnitude of the effective number of turns and the phase angle `orientation`. The magnetic potential (difference) of the coupling model,  $\underline{v}_m$ , and the current of the investigated winding,  $i$ , are then related by:

```
 $\underline{V}_m = (2.0/\pi) * N * i;$ 
```

The factor  $2.0/\pi$  is the consequence of averaging the sinusoidal fundamental wave flux waveform over one pole pair.

### 3.3 Induction Law

Induction law describes the relationship between the time derivative of the magnetic flux and the induced voltage of the investigated winding. The projection of the complex magnetic flux onto the `orientation` times the effective number of turns is equal to the negative terminal voltage.

```
-v = Modelica.ComplexMath.real(
  Modelica.ComplexMath.conj(N)*
  Complex(der(Phi.re),der(Phi.im)));
```

### 3.4 Multi Phase Electromagnetic Coupling

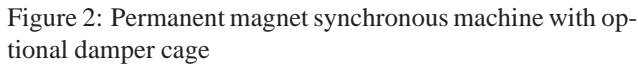

The multi phase electromagnetic coupling model is composed of a vector of  $m$  single phase electromagnetic coupling models, where  $m$  is the number of phases. The  $m$  electrical pins of the single phase electromagnetic coupling model are connected to the  $m$  pins of the electrical multi phases connector used by the multi phase coupling model.

The  $m$  magnetic fundamental wave ports of the single phase electromagnetic coupling models are connected in series. The magnetic series connection is a consequence of, first, each winding being exposed to the same magnetic flux wave – but being located spatially on different locations. Second, the total magnetic potential (difference) excited by all windings is determined by the sum of the magnetic potential (differences) of all individual windings.

## 4 Phase Orientations – Winding Axes

In the `FundamentalWave` library only symmetrical  $m$  phase windings are considered. For multi phase systems and windings with phase numbers greater than three two different cases are distinguished, first, the number of phases is divisible by three and second, the number of phases is not divisible by three. The general function `symmetricOrientation` for determining the orientations of windings of an  $m$  phase electric machine is located in the package `Modelica.Electrical.MultiPhase.Functions`:

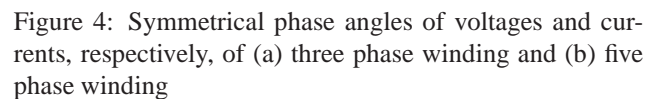

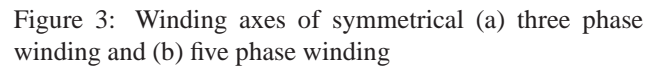

```
function symmetricOrientation
  extends Modelica.Icons.Function;
  input Integer m "Number of phases";
  output Modelica.SIunits.Angle
    orientation[m]
    "Orientation of the resulting
    fundamental wave field phasors";
  import Modelica.Constants.pi;
```

So the function is designed recursively so that subsystems are modularly designed. In the following some examples of phase numbers will be discussed. Two, four, eight, sixteen, thirty-two, etc. phase windings are currently not supported, as in general phase numbers equal to  $2^n$  with integer  $n$  are not considered.

The symmetrically supply voltages and currents, respectively, have the phase angles

138

In the following only symmetrical winding axes will be assumed. The phase angles of symmetrical voltage and current supply are also presented, even though symmetric supply is not assumed in the FundamentalWave library.

For all odd phase numbers  $m$  (not divisible by 2) the symmetrical orientations of the winding axes are

So this applies for the case  $m = 3, m = 5, m = 7, m = 9, m = 11, m = 13, m = 15$ , etc., see Fig. 3-4.

For even phase numbers unequal to  $2^n$  with integer  $n$ , the  $m$  phase system is separated into two subsystems with  $m/2$  phases. The winding orientations of the second subsystem lags the first subsystem by  $\frac{\pi}{m}$ . This is then the point where the recursive determination of phase angle is initiated. For each of the two subsystems `symmetricOrientation` is called, considering the lag angle  $\frac{\pi}{m}$ . It is important to explicitly note that the phase shift be-

tween the two sub systems is not  $\frac{2\pi}{m}$ , since in this case the

Figure 5: Winding axes of symmetrical (a) six phase winding and (b) ten phase winding

Figure 6: Symmetrical phase angles of voltages and currents, respectively, of (a) six phase winding and (b) ten phase winding

two sub systems where aligned at  $\pm\pi$  which does not make sense in a technical system for redundancy reasons.

A **six phase system** is then separated into two three phase systems. The winding orientations of the second sub systems lags the first sub system by  $\pi/6$ , see Figs. 5–6. The phase sequences (1-2-3) and (4-5-6) of the two sub systems are equal.

A **ten phase system** consists of two five phase systems with the phase sequences (1-2-3-4-5) and (6-7-8-9-10). The second sub systems lags the first sub system by  $\frac{\pi}{10}$ , see Figs. 5–6.

### 4.3 Phase Numbers Divisible by Three

Phase numbers divisible by three are either covered by subsection 4.1 and 4.2. Therefore, from a formal point of view no additional explanations are required to handle, for example, nine phase machines. Yet, a typical engineering approach and function `symmetricOrientation` for numbering the phase numbers are different and may require some additional comments:

Practically, in most technical cases, electrical machines with phase numbers divisible by three will be supplied by an appropriate number of three phase inverters. For six phase systems this has already been demonstrated in subsection 4.2. In the FundamentalWave library nine phase systems are handled differently only in that sense, the sequence numbering the phase windings is most likely different from an engineer who uses three three phase inverters. In the engineering phases (1-2-3) are most likely assigned to the first inverter, phases (4-5-6) are assigned to the second inverter and phases (7-8-9) are assigned to the third inverters, see Fig. 7(a). In the FundamentalWave library the phase are

Figure 7: Numbering of nine phase symmetrical winding according to (a) an engineering approach using three three phase inverters and (b) the scheme of the FundamentalWave library

numbered according to Fig. 7(b). Even though the numbering is different the angles of the orientations are fully identical.

For a fifteen phase a design engineer could always argue whether such system can be seen as five three phase systems or as three five phase systems. However, from operating conditions point of view, there is no difference between these two cases. The numbering scheme of the FundamentalWave follows a formal scheme and the user decides how the machine phases are supplied.

## 5 Magnetic Components

All the existing magnetic components of the FundamentalWave library can be re-used for the multi-phase machine models, since the magnetic port representation did not change. In the current implementation only linear magnetic materials are considered. Saturation effects are not taken into account.

In all electric machine models of the FundamentalWave library the total magnetic reluctance is concentrated in the air gap model. An example of permanent magnet synchronous machine with optional damper cage is displayed in Fig. 2. In the actual implementation of the FundamentalWave library the magnetic reluctances of the stator, rotor and air gap are not individually modeled. Even the linear characteristic of the permanent magnet is represent by the total air gap reluctance of the machine. The total reluctance takes the variable reluctance of the air gap length  $\delta$  into account. A sketch of the air gap and the reciprocal function  $1/\delta$  are shown in Fig. 8.

The effect of variable magnetic reluctance due to the uneven shape of the air gap and the arrangement of magnets, respectively, is called saliency. The effect of saliency on fundamental wave forms is fully considered by unequal direct ( $d$ ) and quadrature ( $q$ ) axis reluctances. For rotor fixed magnetic flux  $\Phi$  and total magnetic potential difference  $v_m$  the following relationship applies:

$$\begin{aligned} (\pi/2.0)*V_{m.re} &= \Phi_{re} * R_{m.d}; \\ (\pi/2.0)*V_{m.im} &= \Phi_{im} * R_{m.q}; \end{aligned}$$

The  $d$  and  $q$  axis are, however, fixed with the rotor structure. Magnetic rotor excitation of synchronous machines is, however, always aligned with the  $d$  axis.

Figure 8: (a) Variable air gap length  $\delta$  of a synchronous machine and (b) reciprocal air gap function  $1/\delta$  versus spatial angle  $\phi$  of an equivalent two pole machine

Quantity	$m_s = 3$	$m_s \geq 3$
Nominal stator phase voltage	$V'_{sN}$	$V_{sN} = V'_{sN}$
Nominal stator phase current	$I'_{sN}$	$I_{sN} = I'_{sN} \frac{3}{m}$
Nominal stator frequency	$f'_{sN}$	$f_{sN} = f'_{sN}$
Nominal electrical torque	$\tau'_N$	$\tau_N = \tau'_N$
Nominal electrical stator power	$P'_{sN}$	$P_{sN} = P'_{sN}$

Table 1: Parameters of machines with phases numbers equal and greater than three

In case that the saturation characteristics of the different regions of the machine shall be considered in the future, the magnetic equivalent circuit has to be adapted such way that each region is then represented by one non-linear reluctance.

## 6 Parametrization

Where do the parameters of a machine with  $m_s$  stator phases come from? First, in the design stage of the machine, an engineer determines these parameters from finite element analysis or any other electromagnetic design software. Second, the parameters of a three phase machine are known or estimated and the users wants to determine the parameters of an equivalent  $m$  phase machine. The equivalence then often refers to equivalent speed, frequency, torque, power, phase voltage, power factor and efficiency. For the second case the exact calculations will be provided in the following:

Assume, the nominal parameter of a three phase and arbitrary  $m$  phase machine as listed in Tab. 1. All the parameters of a three phase machine are indicated with '. According to the relationship between the  $m$  phase nominal phase voltage and current, all resistances and inductances of an  $m$  phase machine are scaled with  $m/3$ . A list of relevant parameters is summarized in Tab. 2.

The rotor winding of squirrel cage induction machines are implemented as equivalent  $m_s$  phase windings – where  $m_s$  is the number of stator phases. Slip ring induction machines may have different phases numbers of stator and rotor – where  $m_r$  is the number of rotor phases. For synchronous machines with permanent magnets, electrical excitation and reluctance rotor, the optional damper cage is implemented

Quantity	$m = 3$	$m \geq 3$
Stator resistance	$R'_s$	$R_s = R'_s \frac{m}{3}$
Stator stray inductance	$L'_{s\sigma}$	$L_{s\sigma} = L'_{s\sigma} \frac{m}{3}$
Main field inductance	$L'_m$	$L_m = L'_m \frac{m}{3}$
Main field inductance, $d$ -axis	$L'_{md}$	$L_{md} = L'_{md} \frac{m}{3}$
Main field inductance, $q$ -axis	$L'_{mq}$	$L_{mq} = L'_{mq} \frac{m}{3}$

Table 2: Stator parameters of three and  $m_s \geq 3$  phase machines

Quantity	$m = 3$	$m \geq 3$
Induction machine with squirrel cage		
Rotor cage resistance	$R'_r$	$R_r = R'_r \frac{m_s}{3}$
Rotor stray inductance	$L'_{r\sigma}$	$L_{r\sigma} = L'_{r\sigma} \frac{m_s}{3}$
Induction machine with slip ring rotor		
Rotor cage resistance	$R'_r$	$R_r = R'_r \frac{m_r}{3}$
Rotor stray inductance	$L'_{r\sigma}$	$L_{r\sigma} = L'_{r\sigma} \frac{m_r}{3}$
All synchronous machines		
Damper cage resistance, $d$ -axis	$R'_{rd}$	$R_{rd} = R'_{rd}$
Damper cage resistance, $q$ -axis	$R'_{rq}$	$R_{rq} = R'_{rq}$
Damper cage stray inductance, $d$ -axis	$L'_{r\sigma,d}$	$L_{r\sigma,d} = L'_{r\sigma,d}$
Damper cage stray inductance, $q$ -axis	$L'_{r\sigma,q}$	$L_{r\sigma,q} = L'_{r\sigma,q}$

Table 3: Rotor parameters of machines with three and  $m_s \geq 3$  and  $m_r \geq 3$  phases

with salient rotor parameters with respect to the direct ( $d$ ) and quadrature ( $q$ ) axis. So there is no difference between three and multi phase damper cage models and parameters. The rotor cage parameters of all machine types are summarized in Tab. 3.

## 7 Examples

In the FundamentalWave library there are examples for all types of machines, comparing three phase and multi phase ( $m = 5$ ) machines. The three and five phase machines are operated with equal nominal phase voltages. The parameters of the five phase machine are parameterized such way automatically that the phase number can be increased without changing torques and powers for the multi phase machines. In a duplicate example the phase numbers can be changed for from five to higher numbers.

The following examples are included in the FundamentalWave library:

### 7.1 Induction Machine with Squirrel Cage

In model `Examples.AIMC_DOL_MultiPhase` two asynchronous induction machines with squirrel cage rotor are started directly on line (DOL) by means of an ideal switch; see Figure 9. The machines start from standstill.

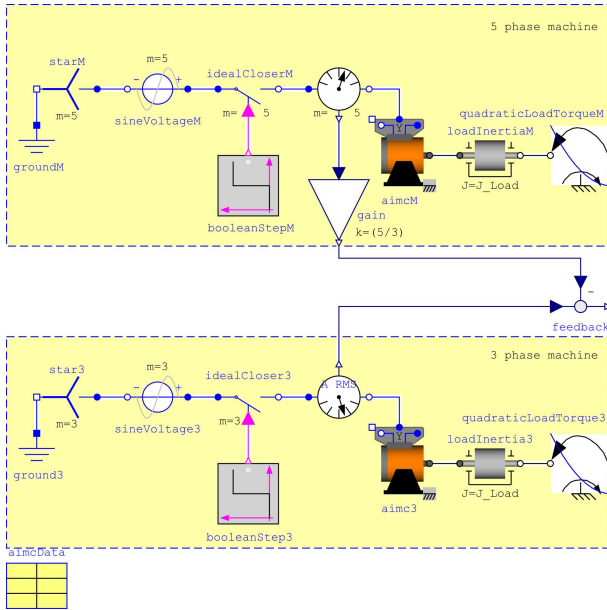

Figure 9: Comparing a three and a multi phase ( $m = 5$ ) permanent magnet synchronous machine, operated on an idealized voltage inverter

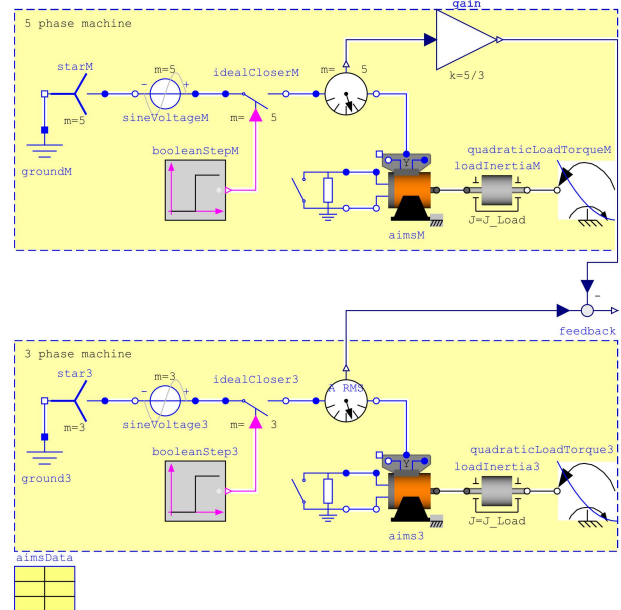

Figure 12: Comparing a three and a multi phase ( $m = 5$ ) induction machine started directly on line, operated on an idealized voltage inverter

Figure 10: Simulation result of electrical torque of a three and five phase squirrel cage induction machines; the torques are equal

Figure 11: Simulation result of the quasi RMS currents of a three and five phase squirrel cage induction machines; the current ratio is five to three

The mechanical load is modeled by means of a quadratic speed dependent load torque and an additional load inertia. This example demonstrates equivalent dynamic behavior of the three and five phase machine. Particularly, the electrical torque, speed, and the particular losses are equal.

Both machines have the same nominal phase voltage, but different nominal phase currents according to Tab. 1. In Fig. 10 the two identical electric torques of the two machines are shown. The different quasi RMS currents of two machines are displayed in Fig. 11. The current ratio is equal to five over three.

## 7.2 Induction Machine with Slip Ring Rotor

Model Examples.BasicMachines.AIMS\_Start\_MultiPhase compares a three and a five phase slip ring induction machine, operating the stator direct on line; see Fig. 12. The number of stator phases  $m_s = 5$  and the number of rotor phases,  $m_r = 5$ , are equal. The multi phase rotor windings of each machine are connected with a rheostat which is shorted after a give time period  $t_{\text{rheostat}} = 1.0$  second. The rheostat enables a greater starting torque – but worse efficiency. Therefore, after one second, the rheostats are shorted to achieve a higher efficiency and speed of the machines. The user can copy the example and change the rotor phase number  $m_r$  such way that it differs from the stator phase number,  $m_s$ . This case is also supported the FundamentalWave library. In Fig. 13 and 14 the electromagnetic torques and the quasi RMS currents of the two machines are compared. The torques are identical and the current ratio is five to three according to Tab. 1.

Figure 13: Simulation result of electrical torque of a three and five phase slip ring induction machines; the torques are equal

Figure 14: Simulation result of the quasi RMS currents of a three and five phase slip ring induction machines; the current ratio is five to three

### 7.3 Synchronous Generator with Electrical Excitation

In example `Examples.SMPM_Generator` two mains supplied electrical excited synchronous machine with three and five stator phases are compared; see Fig. 16. For each machine shaft speed is constant and slightly different than synchronous speed. In this experiment each rotor is forced to make a full revolution relative to the magnetic field. In Fig. 16 the generated torques versus load angle are shown for a fixed level of excitation. In addition to the sinusoidal waveform of the torque a second harmonic component is superimposed due to the saliency of the rotor. However, for the investigated machines, the saliency effect is very small so that the torque waveform almost appears as a pure sine wave. The quasi RMS currents of the two machines are compared in Fig. 17. The current ratios of the three and five phase machine is five to three.

Figure 15: Comparing a three and a multi phase ( $m = 5$ ) permanent magnet synchronous machine, operated on an idealized voltage inverter

Figure 16: Simulation result of electrical torque, comparing a three and five phase

Figure 17: Simulation result of the quasi RMS currents of a three and five phase synchronous machine with electric excitation; the current ratio is five to three

## 8 Conclusions

The paper presents an extension of the FundamentalWave library towards multi phase stator (and rotor) windings with phase numbers greater or equal than three. This library is included in the MSL 3.2.1. Assumptions and limitations of the presented implementation are explained. In the new FundamentalWave library only symmetrical windings are supported. The structures of symmetrical multi phase windings and supplies are introduced.

The parametrization of the multi phase machines is discussed. Conversion tables for parameterizing multi phase machines equivalent to three phase machines are presented. Simulation examples of three and equivalent five phase induction and synchronous machines are presented and compared.

## Abstract

A new quasi static fundamental wave machines library will be included in the magnetic domain package of the next Modelica Standard Library (MSL). The provided classes of machine models omit all transient electrical effects, but mechanical dynamics are fully taken into account. By including the new machine models new classes of problems can be treated, enabling fast electric machine and drive simulations. Yet, all the characteristic loss effects of transient machine models are fully taken into account, where needed. Phase numbers greater than three are supported. For each machine type available in the MSL there will then exist both a fully transient and a quasi static electric machine model. The package structure of the quasi static fundamental wave package and the concept of implementation will be presented. All required assumptions and limitations for operating the new machine models will be presented and discussed. Deviating parameters compared to the transient machine models will be discussed and explained. Simulation examples will be presented and compared with transient simulation experiments. Possible applications for the new machine models will be outlined.

*Keywords: Quasi static fundamental wave electric machine models, multi phase, transient effects, reference frame*

## 1 Introduction

The investigation of electric machine transients is highly relevant for designing drive controls and investigating complex multi domain physical systems. Yet, in many applications the full electrical transients play a minor role. For example, the investigation of electric driving cycles of full or hybrid electric vehicles or railways or the assessment of auxiliary drives or the superior control of multiple drives in an industrial environment do not require the full consideration of all electrical transients. In such cases it is assumed that machine control is designed and implemented such way that electric transients have no significant impact either on power and energy balance or on the overloading capability or stability. Additionally, it may even be requested or required to reduce system complexity for such applications

by eliminating electrically transient phenomena. The newly developed quasi static fundamental wave electric machines library is closing the gap for fast, simple and accurate electric machine models in a Modelica simulation environment. The new quasi static fundamental wave electric machines library is designed in the style of the transient FundamentalWave library [1] which is already included in the Modelica Standard Library (MSL). The new library utilizes the existing quasi static multi phase electric package as well as the rotational mechanics and the thermal domain [2]. All machine models are strictly object oriented: Modelica classes for windings, air gaps, linear magnetic reluctances, losses, etc. are provided. From a didactic point of view the quasi static magnetic field theory enables valuable insight into electro magnetic and mechanic power conversion. Additionally, the provided linear machine models are designed such way that they can be extended towards non linear magnetic effects such as saturation or permanent magnet (PM) demagnetization. When designing the new library it was intended to include as much features as provided by the transient machine models. Therefore, phase numbers greater than three and different phase numbers in the stator and the slip ring rotor of induction machines are fully supported. Yet the number of phases,  $m$ , being equal to  $2^n$  with integer  $n$  are currently not included. The reason for omitting such phase numbers is caused by the fundamental difference of windings systems with  $m = 2^n$  from other windings.

An alternative concept for modeling quasi static magnetic machines in Modelica is presented in [3]. In this concept an induction machine model is presented based solely on electric and magnetic quasi static equivalent circuits. Electro mechanical power conversion is not yet included in this proposal.

## 2 Connector Concept

From a formal point of view the connector concept of the transient and the quasi static fundamental wave package look very similar. The magnetic port consists of the complex magnetic potential,  $\underline{V}_m = V_{m, \text{re}} + jV_{m, \text{im}}$ , and the complex magnet flux,  $\underline{\Phi} = \Phi_{\text{re}} + j\Phi_{\text{im}}$ .

```
connector MagneticPort
  "Basic quasi static magnet connector"
```

Figure 1: Stator and rotor fixed reference frame of an electric machine

```

Modelica.SIunits.ComplexMagneticPotential
  V_m "Complex magnetic potential
    at the node";
  flow Modelica.SIunits.ComplexMagneticFlux
    Phi "Complex magnetic flux flowing
    into the pin";
end MagneticPort;
    
```

The complex magnetic potential and the complex magnetic flux represent a spatial fundamental wave field distribution given by:

$$\begin{aligned}
 \Phi(\varphi) &= \text{Re}[(\Phi_{\text{re}} + j\Phi_{\text{im}})e^{-j\varphi}] \\
 &= \Phi_{\text{re}} \cos(\varphi) + \Phi_{\text{im}} \sin(\varphi) \\
 V_m(\varphi) &= \text{Re}[(V_{m,\text{re}} + jV_{m,\text{im}})e^{-j\varphi}] \\
 &= V_{m,\text{re}} \cos(\varphi) + V_{m,\text{im}} \sin(\varphi)
 \end{aligned}$$

A visualization of the fundamental wave forms is illustrated in [1].

The main difference is the reference angle included in both the quasi static positive and negative connector class definition.

```

connector PositiveMagneticPort
  "Positive magnetic port"
  extends QuasiStaticFundamentalWave.
    Interfaces.MagneticPort;
  Modelica.Electrical.QuasiStatic.
    Types.Reference reference "Reference";
end PositiveMagneticPort;
    
```

The reference angle represents the angle of the reference frame that the connector refers to. In electric machines typically stator and rotor reference frames are used in which the fundamental principles of Ampere's law and induction law apply. The stator of electric motors are either supplied by a fixed or variable frequency source. Stator frequency determines the stator reference angle. The frequency of the induced voltages of the rotor depends on the machine type and whether the winding is accessible from the outside. In case of a synchronous generator stator frequency is determined by the rotational speed.

Stator and rotor reference frames with respect to a complex magnetic flux phasor are depicted in Fig. 1. The complex phasor consists of a real and imaginary part, in the respective reference frame. The different reference frames are, however, indicated by the reference angle provided by the connector. So when coupling the stator and rotor fixed reference frame over the air gap model the real and imaginary

parts of magnetic flux are the same. Only the reference angles are different. The very same applies for the complex magnetic potential difference.

In Fig. 1 (s) represents the stator fixed reference frame and  $\gamma_s$  is the angle difference between connector reference frame and the stator fixed reference frame. In the same way, (r) represents the rotor fixed reference frame and  $\gamma_r$  is the angle difference between connector reference frame and the rotor fixed reference frame. The angle difference

$$\gamma = \gamma_s - \gamma_r$$

is equivalent to the rotational mechanical angle between stator and rotor, multiplied by the number of pole pairs,  $p$ .

### 3 Assumptions and Limitations

First, in the actual version of the quasi static fundamental wave library the phase number  $m$  must not be equal to  $2^n$  for integer  $n$ .

Second, the used electric connector is based on the package `Modelica.Electrical.QuasiStatic.MultiPhase`. Therefore, only single frequency voltages and currents are taken into account in the underlying electrical connector concept.

The third limitation is that only symmetric voltages and currents are allowed for supplying and loading the machines. This restriction is a consequence of the fact that unbalanced voltage and current supply, respectively, cause forward and backward spinning magnetic field waves. In the squirrel cages of induction machines the backwards spinning field waves give rise to slip dependent frequency components in the voltages and currents which cannot be taken into account by the single supply frequency approach of the quasi static multi phase connector. When investigating the power flow and systemic behaviors of mains supplied electric machines any supply asymmetrical is usually of minor interest. For variable speed inverter fed electric machines symmetrical voltage supply can be assumed due to the control of the power electronics which strictly avoids voltage asymmetries.

Fourth, all windings are assumed to be fully symmetrical. So the numbers of turns are equal for all winding axes and the winding axis orientations are strictly related with the function shown in Listing 1.

Fifth, due to the assumed symmetry of supply voltages and currents, zero voltages, zero currents and zero impedances are not considered in the quasi static machine models.

Sixth, all the magnetic reluctances of the machine models are assumed to be constant. This represents a strictly linear relationship between magnetic potential differences and magnetic fluxes.

### 4 Library Structure and Components

The structure of the new quasi static fundamental wave library is presented in Fig. 2. The key components such as

Figure 2: Structure of the quasi static fundamental wave library

the electro magnetic coupling, the salient air gap model and the damper cage concept which will be presented in the following subsections. The coupling models rely on the symmetry of voltages and currents. Therefore, symmetrical components are discussed in this section as well. Cage models, the PM model, regular reluctance and eddy current models are designed in the style of the transient fundamental wave library and need no particular attention in this paper. More detailed model descriptions can be found in [1]. Parametrization rules for multi phase machines with phase numbers greater or equal to three are described in [4].

## 4.1 Symmetrical Components

The orientations of the winding axes of an  $m$ -phase system is defined by the function listed in Listing 1, which is also used in the transient fundamental wave library.

Listing 1: Function symmetricOrientation

```
function symmetricOrientation
  "Orientations of the resulting
  fundamental wave field phasors"
  extends Modelica.Icons.Function;

  input Integer m "Number of phases";
```

```
output Modelica.SIunits.Angle
orientation[m]
"Orientation of the resulting
fundamental wave field phasors";

import Modelica.Constants.pi;

algorithm
  if mod(m, 2) == 0 then
    // Even number of phases
    if m == 2 then
      // Special case two phase machine
      orientation[1] := 0;
      orientation[2] := +pi/2;
    else
      orientation[1:integer(m/2)] :=
        symmetricOrientation(integer(m/2));
      orientation[integer(m/2) + 1:m] :=
        symmetricOrientation(integer(m/2))
        - fill(pi/m, integer(m/2));
    end if;
  else
    // Odd number of phases
    orientation :=
      {(k - 1)*2*pi/m for k in 1:m};
  end if;
end symmetricOrientation;
```

An arbitrary  $m$ -phase system of currents  $i_{[k]}$ , for  $1 \leq k \leq m$ , can be transformed into  $m$  symmetrical components. In case of a fully symmetrical system of currents, only the positive sequence component is non-zero. The positive sequence component is computed by means of multiplying the current vector with the transformation matrix obtained from function `symmetricOrientationMatrix`. The design of the transformation matrix relies on the recursive application of the function presented in Listing 1.

As a consequence of assuming fully symmetrical voltages and currents, respectively, only the positive sequence of voltages and currents arise. In case of even phase numbers more than one positive sequence component will arise. It is thus required to determine the indexes of positive sequence components by means of function `indexPositiveSequence`. All other symmetrical components are equal to zero. Their indexes are determined by function `indexNonPositiveSequence`.

## 4.2 Electromagnetic Coupling

The induction law and Ampere's law are related with the positive sequences of the symmetrical components of voltages and currents. Due to the symmetry of the windings the induced voltages of all positive sequence components are identical. In the quasi static domain the time derivative of the magnetic flux is replaced by a multiplication with the imaginary unit and the angular frequency. The complex total magnetic potential difference is related with the sum of all positive sequence currents, see Listing 2.

    Connections.branch(
    plug_p.reference, port_p.reference);
    plug_p.reference.gamma =
    port_p.reference.gamma;
    ...
end MultiPhaseElectroMagneticConverter;

```

The reference angles of both the electrical and the magnetic domain are connected by means of breakable connections. This concept breaks potential algebraic loops of the electric and magnetic domain. Additionally, both domains are interconnected by a breakable connector as well.

### 4.3 Air Gap

The air gap model consists of two stator and two rotor magnetic ports and two rotational mechanic flanges representing the stator and rotor, respectively. The complex magnetic potential difference and flow quantities of the quasi static fundamental wave stator and rotor connectors are identical. However, the reference angles are different according to Fig. 1.

Rotor saliency is represent by different magnetic reluctances in the  $d$  (direct) and  $q$  (quadrature) axis – with respect to the rotor fixed reference frame. Therefore, the relationships between magnetic potential differences and fluxes have to be expressed in the rotor fixed reference frame: the rotor fixed complex magnetic potential differences and fluxes are obtained by multiplying each of these quantities by  $e^{j\theta_r}$  as shown in Listing 3.

```

The references of the stator and rotor ports are linked through breakable connections. In case of generator operation without mains connection the stator will have to be treated as root.

## 4.4 Damper Cages

For operating mains supplied synchronous machines it is required to enable the optional damper cage. Otherwise the induced rotor voltage for electrical and PM excited synchronous machines cannot perform the expected slow motion rotation. Since the load angle cannot change abruptly due to rotor inertia, the damper cage is required for operating quasi static synchronous machines with mains supply. The operating behavior of the quasi static machine model is yet different since all transient electrical effects are not taken into account.

The optional damper cages of the synchronous machines are equivalent two axis cages with different resistances and inductances in the rotor  $d$  (direct) and  $q$  (quadrature) axis. The squirrel cage of the induction machine model, however, has the same number of phases as the stator. Same stator and rotor phase numbers are chosen since it is usual in engineering approaches to model the squirrel cage equivalent to the topology of the stator winding.

## 4.5 Example Machine Model

Figure 3 shows the permanent magnet synchronous machine model included in the quasi static fundamental wave library. The quasi static electrical domain is colored in light blue, the quasi static fundamental wave domain is light orange. The rotational and the thermal domain are colored in black and red, respectively.

The stray load loss model is directly part of the stator electric circuit. The voltage drop of this model is equal to zero, and loss is considered as torque times angular frequency. The stray load loss is also dissipated through the thermal connector.

The stator winding represents the electro magnetic coupling of the stator winding with magnetic field. The winding model is depicted in Fig. 4. This model consists of symmetrical winding phase resistors, an ideal electromagnetic coupling, a stray field reluctance in the magnetic domain and a loss model representing solely eddy current core loss. Thermal connectors for copper loss and eddy current loss are provided. Winding resistances are modeled temperature dependent, eddy current loss is modeled independent of temperature.

The air gap model couples the stator and rotor magnetic parts of the model. The electromagnetic torque is transmitted to the stator and rotor, respectively. Stator and rotor torques have the same absolute value but different signs. The magnetic saliency of the rotor is considered by different stator inductances with respect to the  $d$  (direct) and  $q$  (quadrature) axis. In the actual implementation the total inductances of the two axes are associated to one reluctance with respect to the  $d$  and  $q$  axis, respectively, only. Partial reluctances of the stator and rotor teeth, slots, yokes, etc. are currently not separated.

In the rotor magnetic circuit an optional damper cage is included. The damper cage model is a two axis model with cage resistances and stray inductances assigned to the two axis – this is the usual parametrization that electrical engineers are using. The damper cage also provides a thermal connector to exchange heat and temperature with an optional thermal model.

The permanent magnet model is currently not considering temperature dependent magnet properties. The total inductance of the machine already includes the reluctance of the permanent magnet. The PM model is thus a constant source of magnetic potential difference, rotated into the rotor fixed reference frame such that the complex magnetic potential difference phasor is aligned with the  $d$  axis. The mechanical flanges of the PM model are required to model the PM loss as equivalent mechanical loss torque times angular velocity.

The inertias, the friction loss model and the heat port and ambient models are the same for the quasi static and the transient fundamental wave machine models.

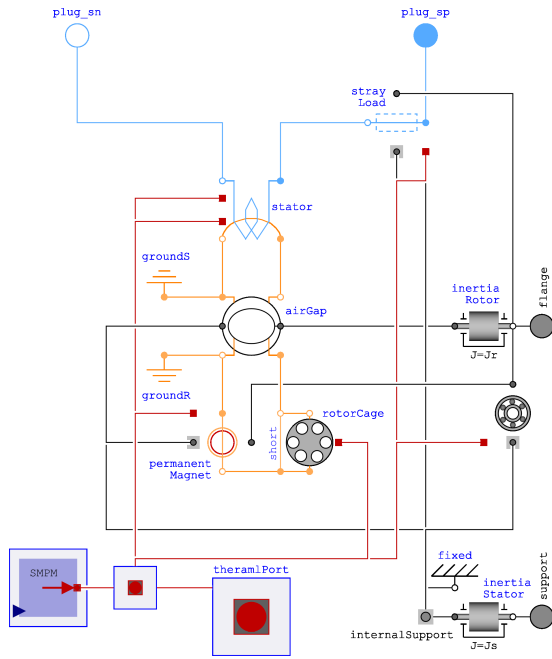

Figure 3: Quasi static model of a multi phase permanent magnet synchronous machine with permanent magnet

## 5 Library Compatibility

### 5.1 Parameter Compatibility

The new quasi static fundamental wave library is almost fully parameter compatible with the transient fundamental wave library. The only incompatibility are the stator zero inductances and the rotor zero inductance of the induction machine with wound slip ring rotor. These zero inductances are not implemented in quasi static machine models. In the transient machine models the default values of the zero inductances are the stray inductances. If the user does not propagate an actual parameter for the zero inductance of a transient machine model, the quasi static and transient machine models can be exchanged without parameter inconsistency.

In the current version of the quasi static fundamental wave library the loss models are fully compatible with the transient machine models. This may change in future versions where quasi static hysteresis loss may be included – which are difficult to implement for transient magnetic fields. Stator core loss, friction loss, stray load loss, permanent magnet loss and brush loss are implemented with compatible parameters and equal static state behavior.

### 5.2 Number of Phases

Parameter compatibility also includes the number of phases. In the quasi static fundamental wave library multi phase machines with phase numbers greater than or equal to three are supported.

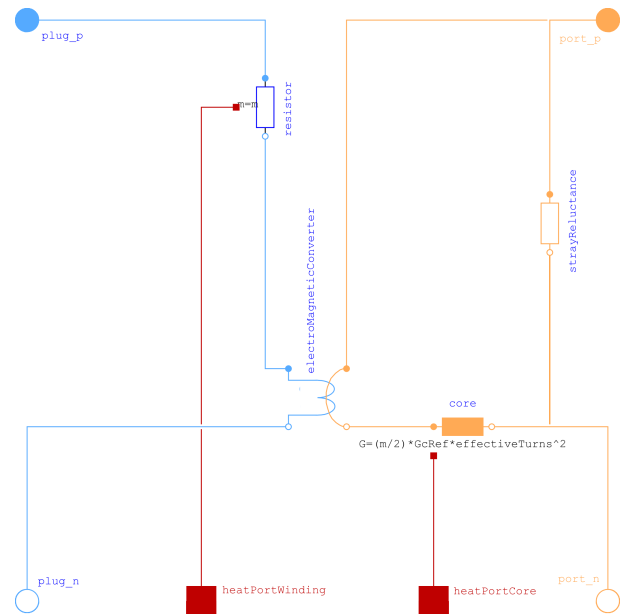

Figure 4: Winding model including winding resistors, electromagnetic coupling, stray reluctances and eddy current loss

### 5.3 Connector Compatibility

The electrical AC multi phase connectors of the transient and quasi static machine model are not compatible due to the different connector designs and properties. The analog DC connector of the synchronous machine with electrical excitation is yet connector compatible. The thermal connectors and the rotational connectors of the shaft and the optional housing, respectively, are connector compatible with the transient machine models.

## 6 Examples

In the following examples of transient and quasi static fundamental wave electric machines are compared. Each of the published examples is also available at the sub package `Examples.BasicMachines`.

### 6.1 Induction Machine with Squirrel Cage Rotor

Starting an induction machine with squirrel cage rotor direct on line shows a transiently higher starting and a lower break down torque than the quasi static machine; see Fig. 5 and 6. The simulation result is not plotted as a function of time, but as parametric plot of torques versus speed. Both machines are loaded with an idealized mechanical load, modeled as quadratic speed dependent torque. The example is available at `Examples.BasicMachines.AIMC_DOL`.

Figure 5: Modelica model of both transient and quasi static squirrel cage induction machine starting directly on line (DOL)

## 6.2 Electrical Excited Synchronous Generator

In example `Examples.BasicMachines.SMEE_Generator` a transient and quasi static synchronous generator with electrical excitation are compared for a very slow load change. The shafts of both generator are spinning with a rotational speed slightly different than synchronous speed, see Fig. 7. Therefore, the rotor is moved over one full electrical revolution – relative to the magnetic field. In the actual Modelica example the total real time of the experiment is equal to 30s. Such an experiment can also be performed in the lab for determining the full torque characteristic as function of the load angle. In Fig. 8 the torques of both machines are displayed versus angle  $\gamma_r$  obtained by the quasi static machine model. Angle  $\gamma_r$  and the load angle  $\vartheta$  are related by

$$\vartheta = \gamma_r - 90^\circ.$$

The torques of both machines are identical due to small relative speed between rotor and magnetic field. The wave form the torque is a sine wave superimposed with a sine wave of half the period due to the rotor saliency of this machine.

## 7 Possible Applications

### 7.1 Long Periods of Simulation Time

The new quasi static fundamental wave models may be used for all time domain simulations covering a large time span. Neglecting electrical transient effects makes the simulation models fast and robust. In particular, large periods of simulation time being in the range of minutes, hours and days, require fast simulation models. In typical simulation applications it is important to model power and energy balances accurately. High accuracy of the actual efficiency is

Figure 6: Torque versus speed for an induction machine with squirrel cage rotor, starting direct on line; comparing transient (trans) and quasi static (QS) machine model; load torque is quadratic speed dependent on speed

Figure 7: Modelica models of synchronous generators with electrical excitation

Figure 8: Torques of the transient and quasi static generator versus angle  $\gamma_r$

enabled by comprehensive loss models included in the machine models of the quasi static fundamental wave library. Typical applications are:

- Drive cycles of full or hybrid electric vehicles
- Drive cycles of subway trains, tramways, and railway trains
- Modeling of mechanical and electrical power and energy balances in industrial processes
- Robot drives for industrial use
- Auxiliary drives

## 7.2 Modularity of Simulation Concepts

Particularly for the simulation of electric machines including power electronics (converter) and control quasi static drive models are an interesting option. Quasi static and transient electric machine models are different levels of abstraction. The two different machine models can be combined with either a quasi static and transient converter models. Both the quasi static and the transient machine and converter can be operated by one control algorithm [5–10]. This way, the level of modularity of electric drives can be increased by means of the new quasi static fundamental wave machine models. The increased modularity reduces maintenance effort for drives libraries and reduces the development time of new or alternative control algorithms, in particular with respect to multi phase electric drives with phase numbers greater than three.

## 8 Didactic Aspects

In the quasi static and the transient fundamental wave library a strictly object oriented modeling approach was pursued. This includes the physical domains electrical, magnetic, rotational and thermal. Due to this approach the models of windings, the air gap and the permanent magnet, etc., can be clearly separated as different objects. In future versions it is even possible to separate the magnetic reluctances of teeth, slots, yokes and magnets.

Quasi static machine models are also of particular interest for high schools and universities to make virtual experiments and to demonstrate the physical behavior of electric machines. The different behavior and quality of quasi static and transient machine models can be discussed and elaborated in classes.

## 9 Conclusions

The new quasi static fundamental wave library for modeling induction and synchronous electric machines is presented. This package shall be included in the next version of the MSL. The provided machine models allow phase number equal to or greater than three. Fully symmetrical windings

and supply voltages and currents are required to fulfill quasi static modeling assumptions.

Additional modeling assumptions and limitations of the library are presented. The compatibility of the quasi static with the transient fundamental wave machine library is discussed. Simulation examples of quasi static and transient machine models are compared.

The new package opens a new field of applications for mobility and industry applications since the quasi static machine models have a very high simulation performance. Possible application examples are presented and didactic aspects of the library are discussed.

## Abstract

Simulation is an indispensable tool for the engineering of systems containing electric drives. Depending on the design phase and the engineering task different levels of modeling details are required: proof of concept, investigation of energy and power consumption, design of control, etc. The new EDrives library provides three levels of abstraction for inverters: quasi static (neglecting electrical transients), averaging (neglecting switching effects) and switching – for serving different demands. The inverters can feed the machine models of the Modelica Standard Library: `Modelica.Magnetic.FundamentalWave` and the new `Modelica.Magnetic.QuasiStatic.FundamentalWave`. The EDrives library copes with arbitrary phase numbers and can be easily extended to develop new control algorithms. In this publication the structure of the library and the implemented control principles are presented. Furthermore, examples comparing the three different levels of abstraction are included.

**Keywords:** *Electric machines and drives, power electronics, control, multi phase, thermal behavior, switching, quasi static, transient*

## 1 Introduction

Engineering of systems containing electric drives is essentially supported by simulation, allowing verification of the overall concept with rapid prototyping against requirements even in early design phases as shown in [1]. Different engineering tasks require different level of modeling abstraction: An early proof of concept can be done without knowledge of details like the control or switching algorithm of the inverter. Determination of energy and power consumption during driving cycles requires the accurate consideration of losses and the interaction of the control with the whole system. Yet, in such cases the switching effects can often be neglected. For more sophisticated investigations of, e.g., the torque ripple, a more detailed model is needed taking switching effects into account. Therefore a modular concept supporting all tasks is indispensable. The new EDrives

library provides inverter models with three levels of abstraction:

- Quasi static inverters connected to quasi static machine models; electrical transients are neglected, but losses are taken into account. The models have highest performance and robustness, making them suitable for long term simulations.
- Averaging inverters connected to transient machine models; the inverter models do not consider switching effects. Interaction of control with the whole system can be tested with high performance. Losses are taken into account, power conversion of the power electronics is based on power balance.
- Switching inverters provide the highest level of abstraction, resulting in lower simulation performance (i.e. longer execution time). On this level of abstraction switching effects and new pulse width modulation algorithms can be investigated.

The EDrives library supports arbitrary phase numbers  $m$  and is thus fully compatible with the `Modelica.Magnetic.FundamentalWave` and the new `Modelica.Magnetic.QuasiStatic.FundamentalWave` library. Yet the number of phases,  $m$ , being equal to  $2^n$  with integer  $n$  are currently not supported. The reasons are discussed in [2] and [3]. Segregating the inverter and the machine models allows the modular exchange with more advanced models of machines, power electronics and control. For example, an electric machine model can be coupled with a thermal model and cooling circuit to study the thermal behavior of the machine and system over a whole driving cycle.

The parameters of the entire drive are compiled in a drive parameter record. The drive parameter record contains a record of the electric machine, the power electronics and the control settings. This modular record structure enables the user to handle and exchange parameter sets for different machines and drives in a very convenient way.

In the actual version of the EDrives library control algorithms are provided for permanent magnet (PM) synchronous machines, solely. Control algorithms for in-

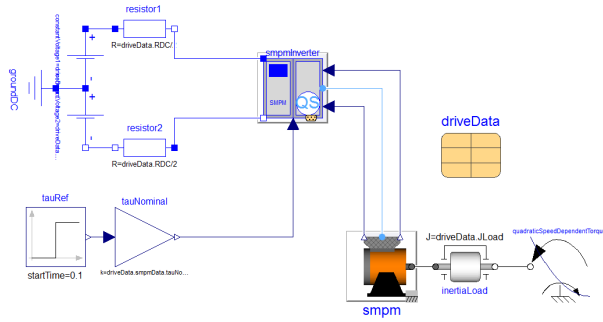

Figure 1: Permanent magnet synchronous machine with inverter

duction machines, electrical excited synchronous and synchronous reluctance machines as well as mains converters feeding the DC intermediate circuit will be implemented in upcoming versions. Therefore, all examples and models presented in this publication refer to permanent magnet synchronous machines.

## 2 Drive Concepts

Each **machine** model provided in the EDrives library consist of a machine model from the MSL including sensors for temperatures and the rotor flange angular position. The interface connectors are electrical, mechanical, thermal and the sensor outputs. These sensor outputs are connected with the inputs of the **inverter** model. The inverter consists of the power electronics, i.e., a **DC/AC converter**, sensors for electrical quantities and machine **control** and pulse width modulation (PWM) if required. The electrical AC output of the inverter is connected with a machine model and the DC input is connected with an external power supply. The type of DC power supply very much depends on the application. The DC power supply may either be a battery or fuel cell or an AC to DC converter supplied by the mains. An example of a PM synchronous machine drive modeled with the EDrives library is shown in Fig. 1. A detailed description of the main drive components is presented in sections 3–6.

## 3 Machines and Sensors

The EDrives library will provide wrapper models for each type of machine to encapsulate the machine model including sensors, as shown in Fig. 2 for a PM synchronous machine. These wrapper models contain:

- an instance of a quasi static or transient machine model of the MSL
- a terminal box, providing the desired terminal connection (star or polygon)
- a rotor angle sensor
- temperature sensors for making stator winding and rotor (PM) temperatures accessible

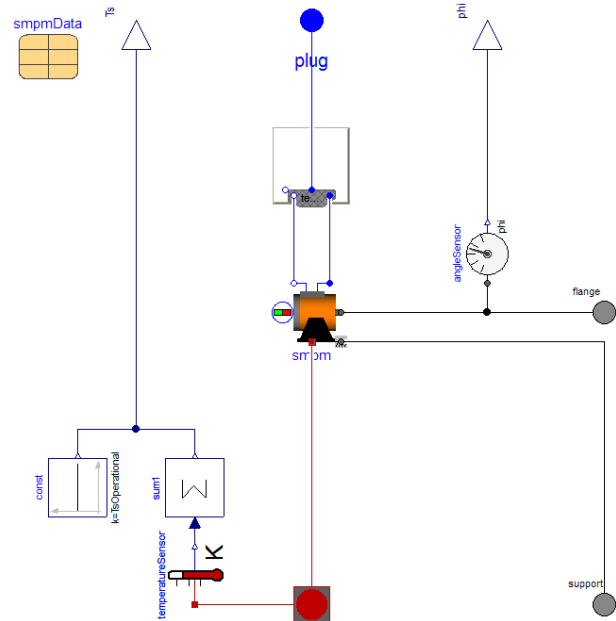

Figure 2: Wrapper model for the transient machine

- the machine parameter record

The machine parameter record allows to propagate all machine parameters with one record. This is achieved by the wrapper model propagating the elements of the parameter record to the machine model. The concept of the wrapper model enables the exchange of a quasi static by a transient machine model in an application and vice versa. The parameter records and all connectors except for the electrical connector are compatible in each wrapper model. This way only the electrical machine supply has to be re-connected. The mechanical flanges, the thermal connector as well as the temperature sensors and angle sensor outputs are the same for all wrapper models of permanent magnet synchronous machines.

Both the quasi static and the transient machine models take losses into account: temperature dependent copper loss, (eddy current) core loss, friction loss, stray load loss and PM loss – see [4, 5]. All these losses are dissipated either to an internal thermal ambient with fixed operational temperature, or exchanged with an external thermal model through the thermal port. An external thermal model allows to simulate the actual temperatures over a driving cycle as discussed, e.g., in [6, 7].

## 4 Inverters and Parametrization

Each inverter model extends from the same base class since they all have the same connectors except for the electrical plug that has to be connected to the machine. However, each inverter model uses the same drive parameter record. Thus, it is possible to replace one inverter model by another in an experiment with low effort. However, the level of abstraction of the machine model has to match level of abstraction of the inverter model: a quasi static inverter can feed a quasi

Figure 3: Switching inverter model

static machine; a transient machine can be supplied by an averaging or by a switching inverter.

The inverter model `converter` shown in Fig. 3 can be one of the following power converter models:

- Quasi static model: considers power balance between DC and quasi static AC side
- Averaging model: provides power balance between DC and transient AC side
- Switching model: the  $m$  phase converter bridge has two electronic switches and two free-wheeling diodes for each leg and phase, respectively

The sensing and signal conditioning of both DC and AC quantities are encapsulated in two models. The DC sensing model retrieves the actual DC current and voltage. Additionally, the filtered DC current, voltage and power are calculated. The filter settings are automatically adapted to the switching frequency of the application.

The AC sensing model acquires AC currents, voltages and power, and calculates the space phasor  $d$  and  $q$  components in the rotor fixed reference frame. These quantities get also filtered to suppress switching frequency related effects. All these quantities are fed to a signal bus, including the actual rotor position.

Machine control is also included in the inverter, as shown in Fig. 3 for a switching inverter model. All the signals obtained by sensors and signal conditioning are provided at the internal bus. Control strategies implemented in the EDrives library rely on field oriented control (FOC). This means that all electrical voltages, electrical currents and magnetic fluxes are decomposed into a component aligned with magnetic field of the PM (direct or  $d$  axis) and a component perpendicular to the magnetic field orientation (quadrature or  $q$  axis). Therefore, the sensed rotor flange

angular position is required to perform the space phasor decomposition. The  $d$  and  $q$  components represent the real and imaginary part of the respective space phasor in the rotor fixed reference frame. The actual orientation and magnitude of the field is obtained by a controller internal machine model. This model also provides the estimated electrical torque. In a real drive application torque and field magnitude and orientation are usually also modeled, not measured. Therefore, the quality of machine control is very much determined by the quality of the controller internal machine model.

For a machine with phase number greater than or equal to three, the electrical voltages, currents and magnetic fluxes are decomposed into space phasors, consisting of a  $d$  and  $q$  component, each. In the EDrives library the signals exchanged between the different controllers are vectors with two components, representing the  $d$  and  $q$  component of a space phasor. This space phasor may either be an electric voltage, current or magnetic flux.

Control is designed hierarchically. On each level of abstraction the control structure includes a torque-flux-controller, see section 6.2. The output of the torque-flux-controller are the commanded  $d$  and  $q$  currents,  $\hat{I}_d$  and  $\hat{I}_q$ . The current of the  $q$  axis is proportional to the generated torque and the  $d$  axis current is used to adjust the actual flux level. These quantities are processed by a current controller. The outputs of the current controller are the components of the commanded voltage space phasor. This space phasor has to be transformed into phase voltages to be provided to the voltage generation of the inverter. Three different levels of inverter abstraction are provided in the EDrives library. The torque-flux-controller, however, is the same for all three levels.

- The quasi static inverter contains a quasi static current controller (section 6.3). The space phasor voltage components are transformed into quasi static phase voltages which are fed to the quasi static power converter.
- The averaging inverter uses a transient current controller (section 6.3) which is also used in the switching inverter model. A delay block is modeling the delay caused by the switching period of a real drive. The space phasor voltage components are transformed into transient phase voltages which are fed to the averaging power converter.
- The switching converter contains the same transient current controller as the averaging inverter. The space phasor voltage components represent the rotor fixed  $d$  and  $q$  components. These components are transformed into the voltage space phasor with respect to the stator fixed reference frame, which serves as input for the PWM (pulse width modulation) algorithm. The switching signals of the PWM are then fed to the  $m$  phase power electronics converter.

The drive parameter record utilized in the inverter model contains the machine parameter record and further param-

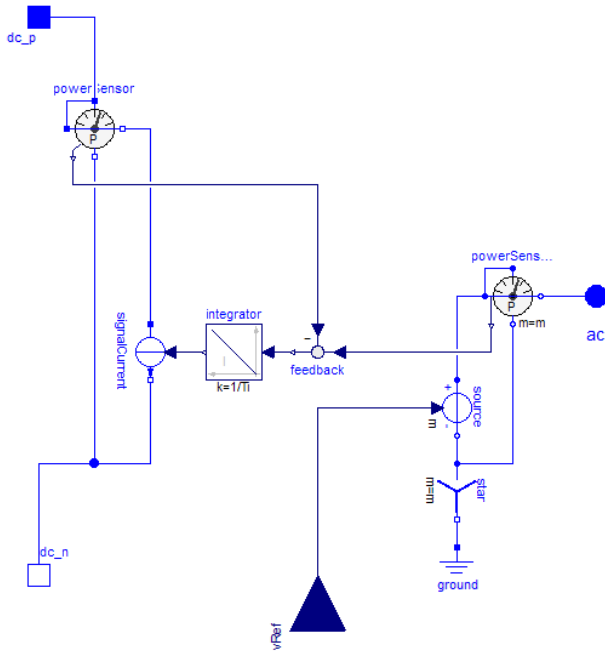

Figure 4: Averaging converter model

eters of the drive configuration. The controller parameters are calculated from the machine parameters and propagated to the controller models. The user can tune the pre-configured control parameters by means of tuning parameters.

## 5 DC / AC Converter

Three different levels of abstraction for DC to AC converters are provided in the EDrives library.

- First, the quasi static converter is modeled as an ideal quasi static voltage source. Power balance between DC input and AC output is complied. This means the efficiency of the quasi static converter is 100 %.
- Second, in the averaging converter model (Fig. 4) the space phasor voltages are transformed into transient phase voltages. These voltages are fed to an ideal voltage source. Considering power balance between DC input and AC output side, the converter efficiency is 100 %.
- Third, the switching converter consists of  $m$  legs. Each of them consists of two electronic switches and two anti parallel free-wheeling diodes. Switch and diode models are taken from the Modelica Standard Library (`IdealGTOThyristor` and `IdealDiode` from package `Modelica.Electrical.Analog.Ideal`). The inputs of the switching converter are boolean switching signals (`on|off`) for each leg.

## 6 Control

Machine control is based on FOC (field oriented control) and consists of the following components:

- optional speed controller
- torque flux controller
- current controller

In each controller model, a space vector representation of voltages and currents in the rotor fixed reference frame is used. These phasors are also distributed to the machine bus. The input for the torque-flux-controller is the commanded torque which can be provided by the user or an optional speed controller.

### 6.1 Optional Speed Controller

The external speed controller is implemented as limited PI controller with anti windup. It feeds the commanded torque via signal connector to the inverter and has to be connected to the inverter via machine bus. The parametrization is defined by a record `speedControllerData` which is a sub-record of the drive parameter record. The record `speedControllerData` calculates the parameters for the PI controller based on the symmetrical optimum method. The subscripts  $iq$  refer to the settings of the current controller with respect to the  $q$  axis [8]:

$$k_p = k_{Tune} \frac{(J_{Machine} + J_{Load}) \omega_{Nominal}}{\tau_{Nominal}} \frac{2k_{Tune,iq}}{T_i}$$

$$T_i = T_{i,iq} \frac{4}{k_{Tune,iq}}$$

### 6.2 Torque Flux Controller

The torque-flux-controller shown in Fig. 5 limits the commanded torque with the maximum speed dependent torque. In the field weakening range torque is limited proportional to one over speed. In the base speed range the maximum torque is constant. The actual machine torque, magnetic flux and stator voltage are determined by a controller internal machine model (section 6.4). The input quantities of the controller internal machine model are the commanded current space vector and the rotor angular position. In a real drive, torque, magnetic flux and stator voltage are either determined by an observer or an on-line model which is implemented in the control software.

The deviation between the commanded and the modeled torque is the input for a fast integrator controlling the  $q$  current component.

The  $d$  current component is determined by the flux controller which implements a simple flux control algorithm. It can be replaced by a more sophisticated flux controller with low effort. First, the actual voltage, calculated by the controller internal machine model is compared with the maximum admissible voltage. This is the minimum of the maximum admissible machine voltage defined by a parameter

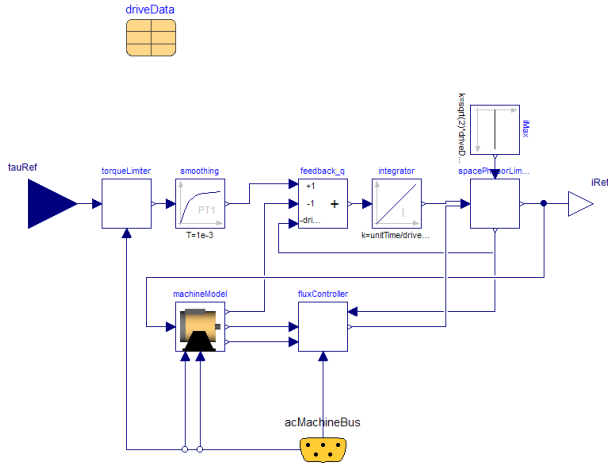

Figure 5: Torque flux controller

and the maximum obtainable voltage according to the actual DC voltage. Second, the actual magnetic stator flux of the machine is compared with the nominal magnetic flux. Nominal flux is calculated by an auxiliary quasi static machine model to determine the nominal operating conditions defined by the machine parameter record. If the actual voltage exceeds the maximum admissible voltage, field weakening occurs. When the actual magnetic flux exceeds the nominal magnetic flux, field weakening ends, entering the base speed range where magnetic flux is kept constant.

In the constant flux region, the  $d$  current component is controlled by a fast integrator to achieve constant magnetic flux. In the field weakening region, the  $d$  current component is determined by the same integrator to keep the voltage limited.

The outputs of the torque-flux-controller are the commanded  $d$  and  $q$  current component of the current space phasor in the rotor fixed reference frame. These components are limited to the maximum admissible machine current, which is defined in the drive parameter record. The limited current space phasor is equal to the commanded current space phasor which is forwarded to the current controller. The commanded current space phasor is also fed to the controller internal machine model.

### 6.3 Current Controller

The current controller for the transient inverters (averaging and switching) utilizes two limited PI controllers with anti windup to determine the stator voltages  $V_d$  and  $V_q$ , respectively. The stator voltage space phasor is determined such way that the commanded currents,  $\hat{I}_d$  and  $\hat{I}_q$ , and the actual currents,  $I_d$  and  $I_q$ , coincide.

The voltage equations of the PM synchronous machine are

$$V_d = R_s \hat{I}_d - \omega L_q \hat{I}_q + L_d \frac{d\hat{I}_d}{dt},$$

$$V_q = R_s \hat{I}_q + \omega L_d \hat{I}_d + L_q \frac{d\hat{I}_q}{dt} + V_{PM},$$

where  $\omega$  is the angular rotor speed. Parameter  $R_s$  represents the stator resistance at rated operating temperature, and  $L_d$  and  $L_q$  are the total inductances of the  $d$  and  $q$  axis. The controller internal machine model determines the voltage drops  $R_s \hat{I}_d + \omega L_q \hat{I}_q$  and  $R_s \hat{I}_q + \omega L_d \hat{I}_d + V_{PM}$ , which are added as feed forward signal to the PI controller outputs. This way the PI controllers solely controls the transient current deviations  $\frac{d\hat{I}_d}{dt}$  and  $\frac{d\hat{I}_q}{dt}$ ; in literature this technique often is called “decoupling”. In the field weakening region the desired voltage space phasor is limited to the maximum admissible voltage (section 6.2).

Since the machine transfer function represents a first order delay, the parametrization of the PI controllers is based on the compensation method [8].

$$k_{p,id} = k_{Tune,id} R_s$$

$$T_{i,id} = \frac{L_d}{R_s}$$

$$k_{p,iq} = k_{Tune,iq} R_s$$

$$T_{i,iq} = \frac{L_q}{R_s}$$

These controller parameters are calculated by the drive parameter record.

The quasi static current controller is simpler: The voltages to match the actual and commanded  $d$  and  $q$  currents are calculated by the controller internal machine model. The complex voltage is limited to the maximum admissible voltage and fed to the output.

### 6.4 Controller Internal Machine Model

The controller internal machine model shown in Fig. 6 is used to calculate the stator voltage phasor, the magnetic flux and torque related to the the commanded stator current space phasor and rotor position. The actual stator winding temperature, however, is taken into account by the controller internal machine model. This machine model is implemented as the instance of a quasi static machine model as described in [3].

Using a quasi static machine model to implement the controller internal machine model is much more structured and modular than an model just implementing text book equations describing the machine’s behavior. Additionally, all improvements of the machine model from the MSL can be utilized. Machine losses and temperature effects are fully taken into account, resulting in a flexible and adaptive machine model.

### 6.5 Space Vector PWM

SVPWM (space vector pulse width modulation) is considered in literature as state of the art PWM, as discussed, e.g., in [9–13]. The PWM block included in the actual version

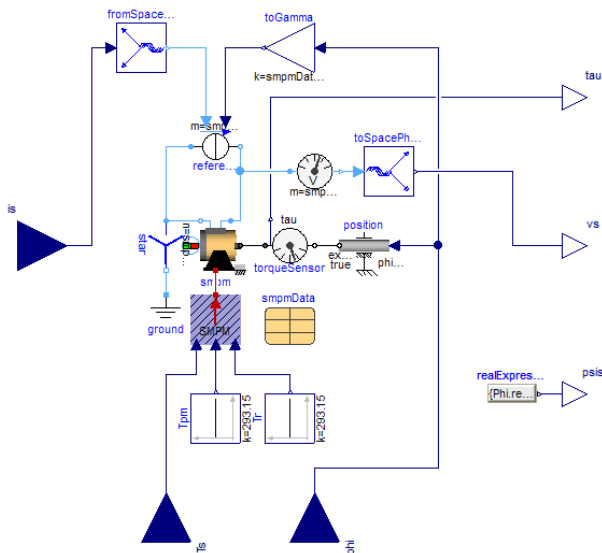

Figure 6: Controller internal machine model

Figure 7: SVPWM switching states in d-q-voltage plane [p.u.] for  $m = 3$  phases

of the EDrives library currently implements a SVPWM algorithm for  $m = 3$  phases. An extension to arbitrary number of phases is under development. The algorithm samples the desired voltage space phasor and the actual DC voltage according to the switching frequency. The possible space phasor locations according to the switching states shown in Fig. 7 are calculated by a function. First, the sector is determined where the commanded voltage space phasor is located. This voltage space phasor can be composed of the two neighbored switching states and either of the two zero switching states. The boolean switching states are fed to the output, to control the electronics switches of the converter (section 5).

## 7 Examples

The first example shown in Fig. 1 simulates a quasi static synchronous machine with permanent magnets, fed by a

quasi static inverter. For the given drive configuration three different levels of abstraction will be compared. First, the original simulation based on the quasi static machine and inverter is performed. Second, the permanent magnet synchronous machine model `smpm` is redeclared as transient machine. Additionally, the inverter model `smpmInverter` feeding the permanent magnet synchronous machine has to be redeclared as averaging inverter. Then an additional simulation run is performed. Third, the averaging inverter is redeclared by a switching inverter.

The machine parameters of the simulation example are derived from the default MSL machine parameters summarized in Tab. 1. No damper cage is used; copper losses are caused by heat dissipation of the stator resistors. All other losses are neglected in the preformed example. The machine is mechanically loaded by an inertia and a quadratic speed dependent torque which reaches nominal torque at nominal speed, representing a fan or a pump. The inverter is connected to a DC voltage source with resistors, simulating a battery. At  $t = 0.1$  s a step from zero to nominal torque is applied to the reference torque input. After accelerating, the drive reaches an equilibrium with the given load characteristic.

The following figures compare the results of

- a transient synchronous machine fed by a switching inverter,
- a transient synchronous machine fed by an averaging inverter and
- a quasi static synchronous machine fed by a quasi static inverter.

In Fig. 8 the actual torques of the three cases follow the reference torque step very well. As expected, the quasi static torque is nearly identical with the reference torque. The switching case shows a torque ripple according to the switching frequency (5 kHz). The speed trajectories in Fig. 9 show only small differences. The plots of the RMS stator currents in Fig. 10 reveal that the  $d$  current increases at  $t = 0$ s to set the nominal magnetic flux. At  $t = 0.1$ s the  $q$  current component is controlled to generate the reference torque. Again the quasi static case shows no transients, whereas the switching current is superimposed by a rest of current ripple left by filtering. The unfiltered phase currents at the end of the simulation are depicted in Fig. 11. A fast Fourier transform (FFT) of phase current of phase 1 is shown in Fig. 12. Note that the largest harmonics – apart from the fundamental wave – are located at multiples of the switching frequency (5 kHz). The filtered stator RMS voltages in Fig. 13 rise with speed since induced voltage increases. Yet the maximum voltage of 100 V is not exceeded. The second example shown in Fig. 14 is derived from the first example, but the number of phases is changed to  $m = 5$ . The desired torque step is replaced by a speed controller which input is a desired speed cycle, and the parametrization of the speed controller is taken from the record `speedControllerData`, embedded in the drive parameter record.

number of phases	$m$		arbitrary
number of pole pairs	$p$		2
rotor's moment of inertia	$J_r$	kg · m <sup>2</sup>	0.29
nominal frequency	$f_{s,Nominal}$	Hz	50
open circuit voltage at nominal speed	$V_{s,OpenCircuit}$	V	112.3
nominal voltage per phase	$V_{s,Nominal}$	V	100
nominal current per phase	$I_{s,Nominal}$	A	$100 \cdot \frac{m}{3}$
stator resistance per phase at 20°C	$R_s$	Ω	$0.03 \cdot \frac{m}{3}$
stator stray inductance per phase	$L_{s\sigma}$	H	$\frac{0.1}{2\pi f_{s,Nominal}} \cdot \frac{m}{3}$
stator main field inductance per phase, d axis	$L_{md}$	H	$\frac{0.3}{2\pi f_{s,Nominal}} \cdot \frac{m}{3}$
stator main field inductance per phase, q axis	$L_{mq}$	H	$\frac{0.3}{2\pi f_{s,Nominal}} \cdot \frac{m}{3}$

Table 1: Machine parameters

Figure 8: Example 1: simulation results of electrical torque

The simulations results are obtained with a transient machine model and an averaging inverter model. Fig. 15 shows the reference torque given by the speed controller and the machine electrical torque. The actual speed follows reference speed very well, as shown in Fig. 16. Fig. 17 shows the 5 phase currents during 1 second of the initial acceleration. This proves that the control system works well in both driving directions, both for motor and generator mode, and for phase numbers  $m > 3$ .

## 8 Outlook

It is planned to release the new EDrives library as commercial tool-independent library. The modular concept of the library supports the following development steps:

- Enhancing the SVPWM algorithm to arbitrary numbers of phases  $m > 3$ .
- Extending both the switching converter model and the SVPWM algorithm to multilevel inverter configurations.
- Considering alternative flux control strategies.
- Implementing the control structures for induction machines with squirrel cage; power electronic converters

Figure 9: Example 1: simulation results of speed

(quasi static, averaging and switching) as well as the SVPWM algorithm can be re-used.

- Providing diode bridge converters as mains converters (quasi static, averaging and switching).
- Developing active mains converters with voltage-oriented control as described in [14]; power electronic converters (quasi static, averaging and switching) as well as the SVPWM algorithm can be re-used.
- In the current implementation, the switching power converter models using the `IdealGTOThyristor` and the `IdealDiode` model from package `Modelica.Electrical.Analog.Ideal` take conduction losses into account. Enhancements include implementation of switching losses for switching power converters, and both conduction and switching losses for averaging and quasi static power converters. One particular focus of development is a user friendly parametrization technique. Furthermore, thermal effects shall be considered, including a thermal port for coupling the electrical models with thermal inverter models and cooling circuits.
- Adaptive control techniques shall be considered, taking temperature dependencies and saturation effects into account.

## 9 Conclusions

The new EDrives library for modeling inverter drives utilizes the machine models from the MSL. The provided in-

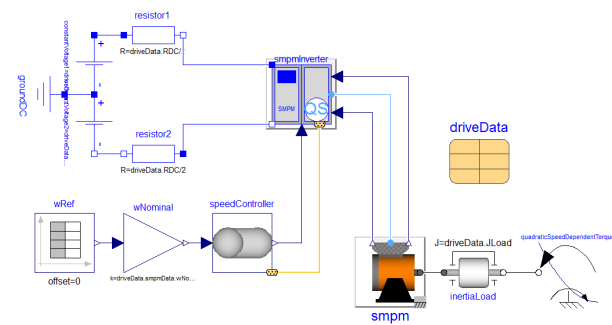

Figure 14: Example 2: speed controlled PM synchronous machine drive

verter models allow phase numbers equal or greater than 3, like the `Modelica.Magnetic.FundamentalWave` and the new `Modelica.Magnetic.QuasiStatic.FundamentalWave`. The control structures are based on FOC. The parametrization of the controllers is described. Simulation examples demonstrate the usage of matching inverter and machine models with respect to different levels of abstraction.

Figure 12: FFT of simulation of stator RMS current at equilibrium

Figure 15: Example 2: simulation results of electrical torque

Figure 16: Example 2: simulation results of speed

Figure 17: Example 2: simulation results of phase currents

The new EDrives library opens a new field of applications for mobility and industrial applications: Quasi static models with highest performance allow long term energy consumption simulations. Averaging models enable testing the interaction of the drive control with the whole system at high performance. The most detailed switching models allow the investigation of ripple effects and the development and customization of controller concepts and designs. The package shall be released as a commercial library, the first version comprises quasi static, averaging and switching inverter models for synchronous machines. Enhancements and extensions are currently under development.

## Abstract

Within the Clean Sky project MoMoLib (Modelica Model Library Development for Media, Magnetic Systems and Wavelets) an extension for the Modelica.Magnetic.FluxTubes library has been developed. This extension mainly consists of new flux tubes elements for the consideration of the magnetic hysteresis in the transient simulation of electromagnetic networks, a materials library with hysteresis data of various magnetic materials and a new components package with models of one- and three-phase transformers, which also account for the magnetic hysteresis of the core. This paper briefly presents the implemented hysteresis models for the simulation of the static (ferromagnetic) and dynamic (eddy currents) hysteresis. It shows the accurate computation of the instantaneous hysteresis losses, which becomes increasingly important for the design of electromagnetic components with increasing requirements regarding energy efficiency and mass power densities. Furthermore, the new components of the library extension are introduced and the behavior of the implemented elements is verified and compared to measurements and steel sheet datasheets.

*Keywords: magnetic hysteresis; Tellinen; Preisach; Modelica.Magnetic.FluxTubes; iron losses;*

## 1 Introduction

The Modelica.Magnetic.FluxTubes library was originally developed at the Technische Universität Dresden and has been part of the Modelica Standard Library (MSL) [1] since 2009. The library is based on the well-known concept of magnetic flux tubes [2, 3] and allows modeling of magnetic fields with lumped networks. Due to the library elements for modeling of coils, non-linear core material, leakage flux and reluctance forces this library is well-suited for the rough design of electromagnetic components and devices, e.g. actuators, motors, transformers, or hold-

ing magnets. Important properties of magnetic components, e.g. saturation behavior, residual magnetism and especially the iron losses are influenced or even determined by the magnetic hysteresis behavior of the involved ferromagnetic materials. Particularly, the consideration of hysteresis losses gets increasingly important during the design process of magnetic components due to increasing requirements on loss power minimization and high mass power densities. Well-known examples of this engineering trend are e.g. the electromobility and more electric aircraft. So far, the ferromagnetic hysteresis is not yet considered in the FluxTubes library. Within a Clean Sky project this issue has been addressed and an extension for the FluxTubes library has been developed. It includes hysteresis elements for the consideration of both static and dynamic hysteresis of ferromagnetic materials. At the Modelica 2012 conference first Modelica hysteresis models have been presented [4]. Now the work on the extension is almost finished and the extended Modelica.Magnetic.FluxTubes library will soon be integrated into the MSL. Two different hysteresis models have been implemented for modeling of static ferromagnetic hysteresis. On the one hand the rather simple but efficient Tellinen model [5], which is characterized by low computational effort and high numerical stability, and on the other hand the more complex but also more accurate and widely accepted Preisach hysteresis model [6]. Dynamic hysteresis is computed by the product of the classical eddy current factor [5, 7], which considers the electrical conductivity and the thickness of magnetic steel sheets, and the time derivative of the magnetic flux density, which causes the formation of eddy currents. To configure the hysteresis models and to adapt them to specific materials the FluxTubes.Material package has also been extended with a package containing hysteresis properties of typical magnetic materials. This data is mainly based on in-house measurements according to DIN EN 60404-2 using a 25 cm Epstein frame. With a series of simulations the behavior of the developed hysteresis models has been verified and compared to published

data of a steel sheet manufacturer as well as to in-house measurements.

## 2 Theory

This section gives a short introduction to the two implemented static hysteresis models, the Tellinen and the Preisach model, and introduces the approach for consideration of eddy currents and hysteresis losses.

### 2.1 The Tellinen Hysteresis Model

The Tellinen hysteresis model [5] is a comparatively simple model for the description of ferromagnetic (static) hysteresis. Thus, it is easy to implement, numerically stable and fast. Even though the model does not have a magnetic memory, its accuracy is sufficient for a wide range of simulations.

To adapt the model to specific material properties (hysteresis shapes) only the hysteresis envelope curve, i.e. the rising  $R(H)$  and falling  $F(H)$  branches of the limiting hysteresis loop, must be provided (see Figure 1). Together with their corresponding slope functions  $r(H)$  and  $f(H)$ , which define the slope of  $R(H)$  and  $F(H)$  with respect to the magnetic field strength  $H$ , the actual slope  $dB/dt$  of the current operation point  $O(h, b)$  is given by equation (1).

Figure 1: Rising  $R(H)$  and falling  $F(H)$  branch of the hysteresis envelope curve and their corresponding slope functions  $r(H)$  and  $f(H)$

$$\frac{dB}{dt} = \begin{cases} \frac{F(H) - B}{F(H) - R(H)} \cdot r(H) \cdot \frac{dH}{dt} & \text{for } \frac{dH}{dt} > 0 \\ \frac{B - R(H)}{F(H) - R(H)} \cdot f(H) \cdot \frac{dH}{dt} & \text{for } \frac{dH}{dt} < 0 \end{cases} \quad (1)$$

### 2.2 The Preisach Hysteresis Model

This section shows the implementation improvements compared to the prior state of the model presented at the 9<sup>th</sup> Modelica conference 2012 [4]. The Preisach model is described in more detail e.g. in [6, 8]. The behavior of the Preisach model results from a superposition of an infinite set of elementary hysteresis operators  $\gamma_{\alpha\beta}$  with the upper and lower switching limits of  $\alpha$  and  $\beta$ , respectively. The operators output equals +1 for a magnetic field strength  $h$  greater than  $\alpha$  and -1 for  $h$  less than  $\beta$ . For all  $h$  between  $\alpha$  and  $\beta$ , the output  $\gamma_{\alpha\beta}h(t)$  remains in the previous state (see equation (2) and Figure 2).

$$\gamma_{\alpha\beta}h(t) = \begin{cases} -1 & \text{for } h(t) \leq \beta \\ +1 & \text{for } h(t) \geq \alpha \\ \text{previous} & \text{else.} \end{cases} \quad (2)$$

Figure 2: Elementary Preisach operator  $\gamma_{\alpha\beta}$  (hysteron).

With the restriction that  $\alpha$  is always greater than  $\beta$ ,  $\alpha$  and  $\beta$  span a right-triangular plane which is often referred to as Preisach plane (see Figure 3).

Figure 3: Preisach plane

For each point  $(\alpha, \beta)$  of this region exactly one elementary hysteresis operator  $\gamma_{\alpha\beta}$  exists with the switching limits of exactly  $\alpha$  and  $\beta$ . The Preisach distribution function  $P(\alpha, \beta)$  is also defined over this Preisach plane and gives a specific weight to each operator (see Figure 4).

The polarization  $j(t)$  of the model is then defined by the integral over all weighted operators outputs multiplied by the saturation polarization  $J_S$ :

$$j(t) = J_S \cdot \iint_{\alpha \geq \beta} P(\alpha, \beta) \cdot \gamma_{\alpha\beta} h(t) d\alpha d\beta. \quad (3)$$

If one splits the Preisach plane into two regions  $S_+$  and  $S_-$ , in which all the operators are in the +1 and -1 state, respectively, equation (3) can be simplified to

$$j(t) = J_S \cdot \left( 2 \cdot \iint_{S_+(t)} P(\alpha, \beta) d\alpha d\beta - 1 \right). \quad (4)$$

It is evident from equation (4) that the Preisach distribution function defines the shape and the behavior of the hysteresis.

Figure 4: Exemplary Preisach distribution function  $P(\alpha, \beta)$  defined over the Preisach plane ( $\alpha \geq \beta$ ).

Normally, the double integral of  $P(\alpha, \beta)$  is not analytically defined. A numerical double integration at every time step of the simulation would be too computationally expensive. In the initial version of the Preisach flux tube element [4] that problem was solved by integrating the Preisach distribution function only once at the start of each simulation for each grid point of a fixed grid over the Preisach plane. The results had been stored in a two-dimensional array (CombiTable2D), which then was used during simulation for table lookup and interpolation to evaluate the integral. The improved version of the element uses now another approach instead, which again improves simulation speed and numerical stability, namely an analytical description of the Everett function [9]. This Everett function  $E_V(\alpha, \beta)$  is defined as the integral of  $P(\alpha, \beta)$  over the region  $R$ :

$$\begin{aligned} E_V(\alpha', \beta') &= \iint_R P(\alpha, \beta) d\alpha d\beta \\ &= \int_{\alpha=\beta'}^{\alpha'} \int_{\beta=\beta'}^{\alpha} P(\alpha, \beta) d\beta d\alpha. \end{aligned} \quad (5)$$

Figure 5 shows the region  $R$  with its integration limits  $\alpha'$  and  $\beta'$ .

Figure 5: Region  $R$  over which the  $P(\alpha, \beta)$  is integrated to compute the Everett function  $E_V(\alpha', \beta')$

The use of this Everett function allows the analytical computation of the Preisach model without numerical integration or a table lookup, thus considerably improving the performance of the developed Preisach flux tube model. The implemented analytical form of the Everett function can be adjusted with seven parameters and thus covers only a limited but a wide range of possible hysteresis shapes.

### 2.3 Eddy Currents

In addition to the previously described static hysteresis models this section explains modeling of dynamic hysteresis, i.e. consideration of eddy currents in a ferromagnetic core. An approach proposed in [5] has been implemented. The total magnetic field strength  $H(t)$  of an hysteresis element consists of a static  $H_{\text{stat}}(t)$  and a dynamic component  $H_{\text{eddy}}(t)$ :

$$H(t) = H_{\text{stat}}(t) + H_{\text{eddy}}(t) \quad (6)$$

$H_{\text{stat}}(t)$  results from the static Preisach or Tellinen hysteresis model.  $H_{\text{eddy}}(t)$  is computed as product of the classical eddy current factor  $\sigma_{\text{cl}}$  [5, 7] and the change of the magnetic flux density in the core.

$$H_{\text{eddy}}(t) = \sigma_{\text{cl}} \cdot \frac{dB}{dt} \quad (7)$$

$\sigma_{\text{cl}}$  results from a homogenization approach. It considers the real electrical conductivity  $\sigma$  and the thickness of individual steel sheets for computation of an adapted conductivity for a whole stack of laminations:

$$\sigma_{\text{cl}} = \frac{\sigma \cdot d^2}{12}. \quad (8)$$

Figure 6 shows exemplarily a simulated hysteresis loop together with its ferromagnetic and its eddy current components. The simulated network model is similar to the one shown in Figure 14.

Figure 6: Simulated biased hysteresis loop  $B(H)$  with its ferromagnetic component  $B(H_{\text{stat}})$  and eddy current component  $B(H_{\text{eddy}})$  for a sinusoidal voltage excitation at 400 Hz

## 2.4 Thermal Losses

Continuous computation of the hysteresis and its static and dynamic components allows for accurate computation of the instantaneous hysteresis losses. The total power loss  $P$  consists of the static hysteresis loss  $P_{\text{stat}}$  and the eddy current loss  $P_{\text{eddy}}$  and can be computed as follows:

$$P = P_{\text{stat}} + P_{\text{eddy}} = H(t) \cdot \frac{dB(t)}{dt} \cdot V. \quad (9)$$

$V$  denotes the core volume. For  $P_{\text{stat}}$  and  $P_{\text{eddy}}$  the equations (10) and (11) apply:

$$P_{\text{stat}} = H_{\text{stat}}(t) \cdot \frac{dB(t)}{dt} \cdot V, \quad (10)$$

$$P_{\text{eddy}} = H_{\text{eddy}}(t) \cdot \frac{dB(t)}{dt} \cdot V = \sigma_{\text{cl}} \cdot \left( \frac{dB(t)}{dt} \right)^2 \cdot V. \quad (11)$$

According to the hysteresis plot of Figure 6, Figure 7 shows the simulated time courses of the magnetic field strength and the core losses together with their static and dynamic components. The function of the magnetic core as an energy storage is easy to recognize in Figure 7 (b). When the loss power is negative, energy is fed back into the system. Furthermore, the instantaneous computation of the power losses is advantageously, because the losses are computed correctly independent of the applied frequencies and waveforms. The total hysteresis losses can be passed to a conditional heat port as a heat flow. This allows for simple integration of the developed hysteresis elements into a thermal network model.

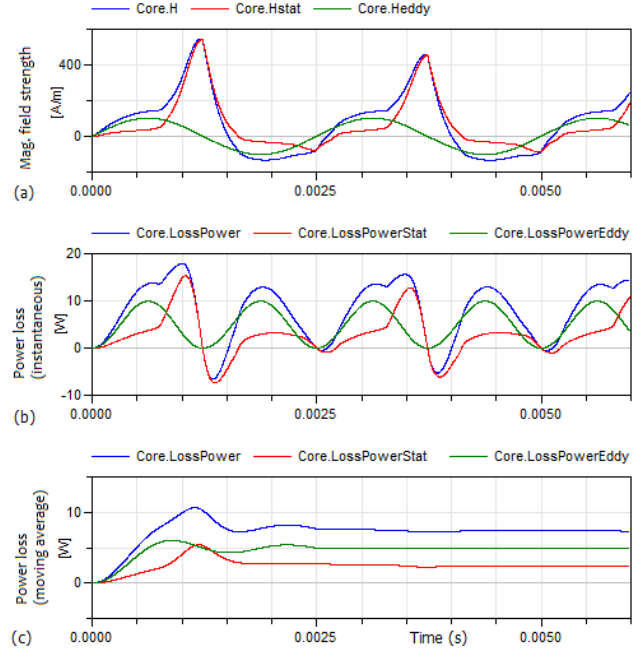

Figure 7: Simulated time course of the magnetic field strength (a), the instantaneous hysteresis losses (b) and the averaged hysteresis losses (c) of a magnetic core element excited with a sinusoidal voltage at 400 Hz (according to the hysteresis plot of Figure 6).

## 3 New Components in the Library Modelica.Magnetic.FluxTubes

The FluxTubes library extension mainly consists of the developed hysteresis elements for modeling of ferromagnetic materials including permanent magnets, an extended materials package and a new components package with models of one- and three-phase transformers.

### 3.1 Package HysteresisAndMagnets

The new hysteresis elements are grouped together in the package FluxTubes.Shapes.HysteresisAndMagnets (see Figure 8). There are four different Tellinen hysteresis models. The difference between these models is the definition of the static hysteresis behavior. The elements CuboidHystTellinenSoft and CuboidHystTellinenHard use very simple hyperbolic tangent shape functions to describe the envelope curve of the hysteresis directly. The shape functions are tailored to the description of soft and hard magnetic materials and can be easily adjusted with four meaningful parameters only (e.g. for the soft magnetic shape functions: saturation magnetization, coercivity, remanence and a multiplier for the vacuum permeability to adjust the slope in the saturation re-

gion). The elements `CuboidHystTellinenEverett` and `CuboidHystPreisachEverett` use the analytical description of the Everett function presented in section 2.2. Several parameter sets to adjust the material behavior are available in the material package `HysteresisEverettParameter`. An additional option to specify the hysteresis shape offers the element `CuboidHysteresisTellinenTable`. This element uses table data for the rising and falling branches of the limiting hysteresis loops, and thus allows for the definition of almost arbitrary hysteresis shapes. Two additional elements for modeling permanent magnets are included in the package: the `CuboidLinearPermanentMagnet` for linear hard magnetic materials defined in `Material.HardMagnetic` and the `CuboidHystTellinenPermanentMagnet` which also accounts for hysteresis and thus also for demagnetisation processes of a permanent magnet.

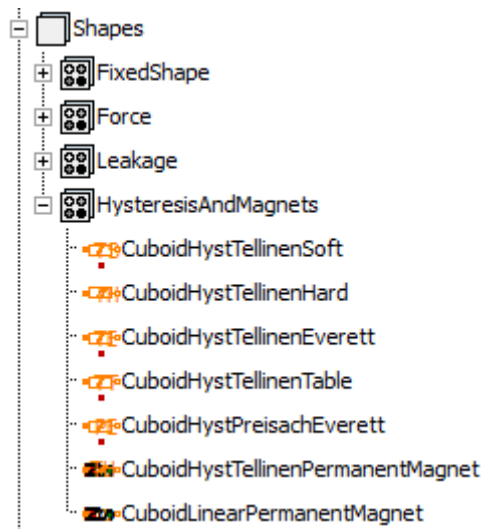

Figure 8: New flux tube elements of package Shapes.-HysteresisAndMagnets

Most of these elements also allow for consideration of eddy currents and provide a conditional heat port, which simplifies delivery of the generated hysteresis losses to a thermal network model.

### 3.2 Package Components

Based on the hysteresis elements described above, package Components contains predefined models of single- and three-phase transformers of different topologies (See Figure 9). The transformer models can be widely configured (e.g. core geometry, winding parameters, stray flux, material) and thus easily be adapted to specific needs. Consideration of both static hysteresis and eddy currents allows for accurate computation of losses, saturation effects, inrush currents and frequency behavior. Again, a conditional

heat port allows for connection of the magnetic model to a thermal network model. Besides the hysteresis losses also the copper losses of the windings are automatically considered.

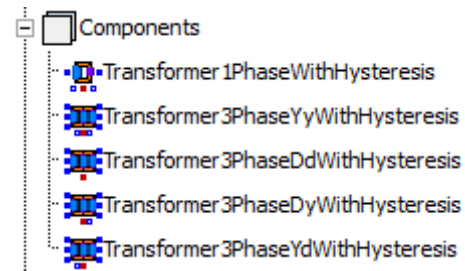

Figure 9: The new Components package of Modelica.Magnetic.FluxTubes.

### 3.3 Extension of Package Material

For a simple adaption of the developed hysteresis models to real magnetic materials two new material packages have been included in the library extension: the package `HysteresisEverettParameter` and the package `HysteresisTableData`. Since accurate hysteresis data is hardly available, a measurement setup has been developed and built for hysteresis characterization of magnetic materials according to the DIN EN 60404-2/4/6. Figure 10 shows the block diagram of the utilized measurement setup. The 25 cm Epstein frame used for the characterization of 30 mm x 280 mm magnetic steel sheet samples is shown in Figure 11.

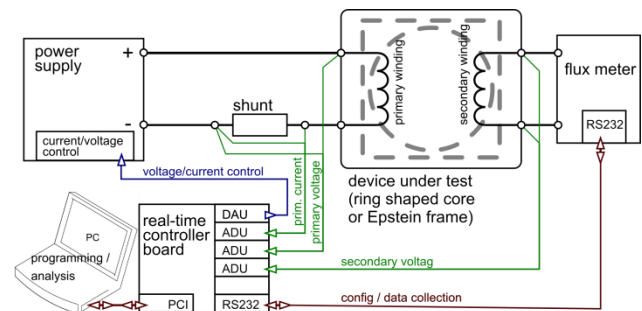

Figure 10: Block diagram of the hysteresis measurement setup

The setup allows hysteresis measurements within a range of the magnetic field strength of  $\pm 10$  kA/m. For the implementation of package material the static hysteresis characteristic of several steel sheet samples has been determined. Three exemplary hysteresis loops for three different steel sheet qualities are shown in Figure 12. For verification of the developed hysteresis models also dynamic loops have been measured.

Figure 11: Built-up 25 cm Epstein frame used for hysteresis characterization of magnetic steel sheets

Figure 12: Exemplarily measured hysteresis loops of three different steel sheet qualities

In package `HysteresisTableData` the measured hysteresis envelope curves are directly stored as table data. The data provided in this package can be used with the `CuboidHystTellinenTable` hysteresis element. Since the hysteresis elements `CuboidHystTellinenEverett` and `CuboidHystPreisachEverett` both need Everett function parameter sets for their configuration (see section 2.2), the package `HysteresisEverettParameter` contains such predefined parameter sets. They have been identified using the hysteresis loops of package `HysteresisTableData` as reference. Figure 13 shows the content of package `HysteresisTableData`. In Addition to the measured hysteresis data some data of cobalt-iron-alloys [10] have also been included in the library. It is planned to extend the material package when new data are available.

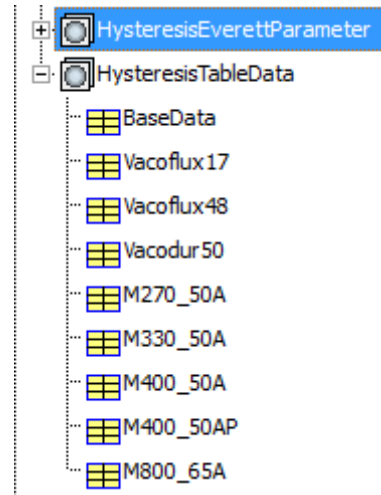

Figure 13: Current content of the hysteresis materials library of Modelica.Magneti.FluxTubes

## 4 Verification Results

To verify the correct simulation of the developed hysteresis models, several experiments have been carried out to compare the model behavior to measurements and to steel sheet datasheets.

### 4.1 Static and Dynamic Hysteresis Loops

In a first experiment the Epstein frame of Figure 11 was used to measure total hysteresis loops (superposition of static and dynamic loops) at several excitation frequencies.

Figure 14: Simple model of the measurement setup including the Epstein frame shown in Figure 11

In addition, the measurement setup has been modeled with a simple model consisting of a sine voltage source, a series resistance, a primary and secondary winding and the magnetic core, latter being modeled with element `CuboidHystTellinenTable` (see Figure 14). The stray flux of the magnetization coils is considered within the element `pWinding`.

Figure 15 shows the measured and the simulated  $B(H)$  loops of the magnetic core for identical excitations at several frequencies. In principal, a good agreement can be seen. The deviations in the 200 Hz loops are likely due to neglect of excess eddy currents, which are not considered in the hysteresis models.

Figure 15: Comparison of measured and simulated total  $B(H)$  loops using M330-50A steel sheets and the Cu-boidHystTellinen hysteresis element for modeling of the core

## 4.2 Time Course of Current and Power Losses

Figure 16: Comparison of measured and simulated primary current and core losses of a transformer excited by a sinusoidal primary voltage of  $U_{pmax}=25$  V and  $f=50$  Hz.

In a second experiment a similar setup and model was used to compare the time course of the primary current and the iron losses. This has been done for a highly saturated core at an excitation frequency of  $f=50$  Hz and a primary voltage magnitude of  $U_{pmax}=25$  V (see Figure 16) and for a moderately saturated core at  $f=100$  Hz and  $U_{pmax}=40$  V (Figure 17).

Figure 17: Comparison of measured and simulated primary current and core losses of a transformer excited by a sinusoidal primary voltage  $U_{pmax}=40$  V and a frequency  $f=100$  Hz

## 4.3 Specific Core Losses

In a third experiment the model of Figure 14 was used again. The sinusoidal primary voltage has been gradually increased at a fixed frequency of 50 Hz for two different core materials. For each step the peak value of the magnetic flux density as well as the average power loss of the core have been recorded. Based on the average power loss, the core volume and the density of the core material the specific total losses of the core material have been evaluated. Figure 18 shows the comparison of these values to manufacturer data, which was extracted from the manufacturer datasheets of the investigated materials [11, 12]. Again, a very good agreement over a wide range of magnetic excitations up to saturation is evident.

## 5 Summary

Within the Clean Sky project MoMoLib an extension of the library Modelica.Magnetic.FluxTubes has successfully been implemented. The extension mainly consists of hysteresis elements for modeling of ferromagnetic and dynamic hysteresis of magnetic

Figure 18: Comparison of specific core losses between data extracted from manufacturer datasheets [11, 12] and simulation results for two different steel sheet qualities M330-50A and M800-65A

materials during transient simulation of electromagnetic components with lumped network models. Two different hysteresis models, the Tellinen and the Preisach model have been implemented. Their static hysteresis characteristics can be parameterized in three different ways: with simple  $\tanh()$  shape functions, hysteresis table data or with parameter sets of an analytical Everett function. A material package, mainly based on in-house measurements, provides the hysteresis data of several magnetic materials for easy parameterization of the models. Dynamic hysteresis is considered with a  $dB/dt$  term. The consideration of static and dynamic hysteresis during transient simulation allows for accurate determination of hysteresis losses. This becomes more and more important during design of electromagnetic actuators and systems due to increasing requirements in terms of power density and miniaturization. A series of experiments showed the correct behavior and the accuracy of the developed hysteresis elements. Additionally, based on the hysteresis elements, models for permanent magnets as well as single- and three-phase transformer models have been implemented.

## 6 Acknowledgement

The authors would like to thank the Clean Sky Joint Technology Initiative for funding of the presented work within Project No. 296369 MoMoLib “Modelica Model Library Development for Media, Magnetic Systems and Wavelets”. Additionally, the authors wish to thank Prof. Martin Otter of the German

Aerospace Center (DLR) for his valuable support regarding numerical efficiency of the developed hysteresis models.

## Abstract

Annotations and attributes form an important part of the Modelica language. They are used to include various meta-information such as documentation, external C-code, compilation hints, etc. Given the increasingly wide field of potential applications the set of useful annotations becomes too large to be included in the language specification. Hence we present a proposal how a Modelica modeler may define his own annotations and how such custom annotations can be organized within Modelica libraries. In the long term, the goal is to move the definition of standardized annotation, as well as of attributes, from the Modelica specification to a standard library.

*Keywords: meta-information; custom annotations; optimization setup; Monte Carlo simulation setup; Kalman filter setup; uncertainty setup.*

## 1 Introduction

The main purpose of Modelica is to enable the equation-based modeling of physical systems. In addition to this primary objective, the modeler has to care about the usability of his/her components. This includes a variety of tasks: documentation needs to be written, icons need to be drawn, a 3D visualization has to be provided, and compilers might need hints for generating more efficient code.

All this is meta-information to the actual physical model but as Figure 1 shows, it can account for a major share of the code: For the FixedTranslation component (a rigid rod in 3D Mechanics), the physical modelling contributes only to 14% of all the code. Of course such a comparison is skewed since it is doubtful to compare manually typed equations with auto-generated code for graphical objects but nevertheless the handling of meta-information deserves to be a major concern for the future design of the Modelica language.

An improved solution for meta-information in Modelica becomes necessary since there is a desire to include more and more information into the models. Especially, a model might be used not only in simulation, but in other analysis and synthesis methods, and then additional model-specific data is needed. For example, sensitivity analysis needs uncertainty data for model variables, Monte Carlo simulation needs stochastic distribution data on states and/or parameters, an optimization setup needs the information which parameters and/or input signals shall be optimized, and in which range the optimization shall take place.

To meet these demands, we propose an enhancement to Modelica: custom annotations. But before we address the new proposal, let us look at the current handling of meta-information in Modelica and its weak spots and then formulate the requirements for a new design.

## 2 Handling of Meta-Information

### 2.1 Meta-Information in Current Modelica

The Modelica language (*Modelica Association 2012*) offers currently two devices that are used for meta-information: annotations and attributes.

Standard annotations are defined for a multitude of issues: graphical information for icons and diagrams, GUI-design, documentation, version handling, etc. Here is a typical annotation in a Modelica code. It describes the representation of a parameter in the GUI of the modeling environment and advises the compiler to evaluate this parameter before generating code:

```
parameter RotationSequence sequence
  "Sequence of rotations "
  annotation(Evaluate=true,
    Dialog(tab="Advanced",
      enable=not useQuaternions)
  );
```

Since the information is mostly of no interest for the human reader and an inadvertent manipulation shall be prevented, most modeling environments for Modelica hide annotations from the user by default.

Attributes are also used for meta-information although this information is mostly linked closer to the physical variables (or parameters) of the model: physical units, minimum and maximum boundaries or potential start values for iterative solvers are described by this language construct. The following example contains attributes for the start value, whether they are used for as initial equations, and whether the variable shall be used as state-variable depending on another parameter.

```
SI.AngularVelocity w_a[3] (
  start=Frames.resolve2(R_start,w_0_start),
  fixed=fill(w_0_fixed, 3),
  each stateSelect=
    if enforceStates then
      (if useQuaternions then
        StateSelect.always
      else StateSelect.never)
    else StateSelect.avoid)
```

The two listings above give a quick glance on how meta-information is stored within Modelica. The current solution served fine for more than a decade but it has come to its limitations. We are confronted with two major weaknesses: rising complexity and ambiguity.

The first weakness is simply the sheer amount of definitions that are needed. The current version of the specification devotes already 20 pages for more as 70 annotations and roughly 7 pages for about 10 attributes. The specification is already a long document and further inflation must be prevented. Also

we have to keep in mind that the specification is primarily targeted for tool vendors and not for end-users. Most end-users should not have to consult the specification but rather refer to other material.

The second weak point is that the definition in the specification is often not complete. For example, it is usually not defined on which elements an annotation can be placed and only from context one might deduce that annotation “Evaluate” makes sense only for primitive data types, whereas annotation “documentation” might make sense at many places, but is actually in use only on classes and not on components.

The third weak spot is the ambiguity between the two different concepts. Whether some information belongs to an attribute or to an annotation is not always clear and has often be a discussion point in the design process of the language. For example, stateSelect is an attribute used to tell the compiler which variables shall form the state-space of the model. Evaluation is an annotation and used to tell the compiler which parameters to evaluate beforehand.

Such discussions are often influenced by the differences in which way attributes and annotations can be accessed. Attributes can be set in (even nested) modifiers, annotations cannot. Vendors can specify their own annotations but they are not allowed to do this for attributes.

### 2.2 Meta-Information in other Languages

In (*Zimmer 2008*) the handling of meta-information (here denoted as multi-aspect modelling) is discussed for various other modeling languages such as VHDL-AMS or SPICE3. Then another approach is proposed based on the experimental language Sol (*Zimmer 2009*). Here the modeler is given the opportunity to define his/her own annotations by means of environment packages and then can use them by instantiating the components of this package within pre-specified sections of his model. This is conveniently possible because in Sol components have first-class status (*Burstall and Strachey, 2000*) unlike in current Modelica.

Another (although similar) proposal is discussed in (*Zimmer, 2012*). It is based on another experimental language called Hornblower. Also here annotations can be defined within packages and then used within the models. This concept treats annotations like “loosely attached parameters”. These are parameters that can be set but do not have to be set. This is possible since such parameters were ensured to always have a reference to a default object.

Meta information can also be defined in certain programming languages, especially in Java (Coward 2004): From [http://en.wikipedia.org/wiki/Java\\_annotation](http://en.wikipedia.org/wiki/Java_annotation): “Classes, methods, variables, parameters and packages may be annotated. Unlike Javadoc tags, Java annotations can be reflective in that they can be embedded in class files generated by the compiler and may be retained by the Java VM to be made retrievable at run-time. It is possible to create meta-annotations out of the existing ones in Java”.

General programming languages often cope much better with meta-information than declarative modeling languages because they own suitable data-structures and often contain already sufficient means for introspection. In Python, there are doc-strings for documentation but they are just predefined class members. Also class or function decorators are used to express a meta-construct on an item, but also these constructs are regular language constructs. In Python there is no need to have language constructs solely devoted to meta-information; instead the regular constructs prove to be sufficient. This shows to us that it is a good idea to reuse regular language constructs for meta-information in Modelica as much as reasonable feasible.

### 3 Design Goals

In concrete terms, the following goals shall be reached:

- The modeler must be able to define annotations by him- or herself.
- Existing annotations or attributes shall be defined in the same way and removed from the specification (at least as many as possible). This will require to introduce more powerful data structures in Modelica.
- The annotations shall be organized in packages so that an end-user can browse through them and do not need to address the specification anymore.
- The modeler must be able to apply custom annotations in (nested) modifiers.
- Annotation must never be required to be provided by the user. Annotations and its parts are always meta-information that can be given optionally.
- The proposed design must be backwards compatible so that current code is not broken.
- The proposed design can make some language constructs obsolete that can then be removed from the language in the future.

- It must be specified how the meta-information contained in custom annotations is handled for model-export (for instance FMI).

Based on these goals, we have developed a suitable design for a future version of the Modelica language: *Custom annotations*.

## 4 Design Proposal

The basic idea of our proposal is to use basic Modelica “records” to define custom annotations and then make them better applicable by enabling the use of annotations in modifiers. In this way, new features can be introduced without having to define many new language elements. Note, records are also the basis of nearly all built-in Modelica annotations. A similar concept in (Zimmer, 2012) served as additional starting point. However the transition from an experimental language to a heavily applied language like Modelica demanded several adaptations.

### 4.1 Use of Records within Annotations

Let us look at an example: Here the Modelica package `OptimSetup` shall be used to define an optimization setup for a model and contains the definition of three record classes that each can be applied as custom annotations.

```
package OptimSetup
  record Tuner "Parameter to be optimized"
    parameter Boolean active = true
    "= true, if parameter is optimized";
    parameter Real min
    "Optional minimum value";
    parameter Real max
    "Optional maximum value";
  end Tuner;

  record Minimize
    "Signal that should be minimized"
    parameter Boolean active = true
    "= true, if used as criterion";
    parameter Real demand = 1.0
    "Value/demand is minimized";
  end Minimize;

  record OptimOptions "Default options for
    the optimization setup"
    parameter String method
    "Optional optimizer method";
    parameter Real tolerance = 0.001
    "Tolerance of optimization";
  end OptimizationOptions;

  record SimOptions
    "Default options for simulation setup"
    parameter String method;
    parameter Real stopTime;
  end SimulationOptions;
end OptimSetup;
```

The record and type definitions of package `OptimSetup` can now be used to describe the setup of an optimization. For example, a parameter can be marked to be a “Tuner” that shall be optimized. The following statement

```
parameter Real p1
  annotation(OptimSetup.Tuner(
    active=true, min=-2));
```

indicates that for a default optimization setup for this model, parameter `p1` shall be used as tuner and shall have a constraint `p1 >= -2`. A custom annotation is identified by the full path name of the `Tuner` record class. This defines a new instance of the record, together with a modifier on this record. So, conceptually, this custom annotation is equivalent to the following declaration:

```
OptimSetup.Tuner name(active=true,
  min=-2);
```

and the name of the instance is not defined, because not needed (the identification of the data is via the class name). Exactly in the same way as in a standard declaration, an element of a record needs not to have a default value or a binding equation in its class, and also not in a modifier.

The lookup of a class name inside an annotation is performed on global scope, so always full path names must be given. This simplifies and speeds up the lookup, especially once built-in annotations are defined as custom annotations in a second phase<sup>1</sup>.

A custom annotation can be also defined on a class. Furthermore, custom and built-in annotations can be within the same annotation declaration, by using a comma-separated list as usual. For example:

```
model ControlledDrive
...
  annotation (Documentation(info="..."),
    OptimSetup(
      OptimOptions(tolerance=1e-3),
      SimOptions(stopTime=4.0, tol=1e-6)
    ));
end ControlledDrive;
```

## 4.2 Enabling Annotations within Hierarchical Modifiers

So far the only extension to the current Modelica language has been that regular Modelica records can be used within annotations. Taken for itself, this is already a progress but it does not suffice to provide the desired level of functionality. For many applica-

tions it is important that annotations can be applied within hierarchical modifiers.

Hence we propose to enable the use of annotation statements within hierarchical modifiers. Here, custom annotations can be either newly constructed or an already defined custom annotation can be modified. Let us look at two corresponding examples:

```
MyCar car(p1 annotation(
  OptimSetup.Tuner(active=false)),
  p2 annotation(
    OptimSetup.Tuner(max=4)),
  p3(min=-3) = 5 annotation(
    OptimSetup.Tuner(min=-2, max=3))
);
```

In this example, the already defined `Tuner.active` value of `p1` is modified to `false`. Parameters `p2` and `p3` are assumed to be defined in `MyCar` without any annotation. The declarations above introduce new instances of custom annotation `OptimSetup.Tuner`, and modify these instances with the given values.

Whereas in principle built-in annotations could be applied within hierarchical modifiers too, we propose to restrict this in a first phase because built-in annotations operate on data structures that are unavailable as the standard language elements and then a standard modifier cannot be applied. This is for instance the case for the annotations describing icons that use case records as data elements. For the future, one may solve this problem by enriching Modelica with suitable data structures. This is a topic where discussion is ongoing in parallel.

As with built-in annotations, it is not possible to read and/or use the value of a custom annotation in a Modelica class (only the translator can use the information contained within annotations by either performing appropriate actions or by passing them to its backend).

## 4.3 About the Use of Hierarchical Records

Since regular Modelica records can be used within annotations, this holds also true for hierarchical records. This is per se not problematic but a few details require a discussion.

Let us suppose we add a hierarchical record `OptimSetup` to our previously present `OptimSetup` package:

```
package OptimSetup

record Tuner [...]

record Minimize [...]

record OptimOptions [...]
```

<sup>1</sup> When built-in annotations are defined with custom annotations, it is proposed that they are placed, e.g., in `ModelicaServices.Annotations`, and that this package is inspected first and then the global scope.

```

record SimOptions [...]

record Options
  OptimOptions optOpts =
    OptimOptions(method="sqp");
  SimOptions simOpts;
end Options;

end OptimSetup;

```

The following example model shows a correct way of using the hierarchical record and a wrong way to do it:

```

model ControlledDrive
...
// correct Modelica code
annotation(OptimSetup.Options(
  optOpts = OptimSetup.OptimOptions(
    method="pattern"),
  simOpts(stopTime = 2)
));

// wrong Modelica code
annotation(OptimSetup.Options(
  optOpts(method="pattern"),
  simOpts = OptimSetup.SimOptions(
    stopTime=2)
));
end ControlledDrive;

```

The record `Options` has two element record instances:

The first element `optOpts` is defined with a record constructor. This means there is a binding equation to `optOpts`. Binding equations cannot be modified with a modifier. They can only be replaced by another binding equation. Therefore in the “correct” code, a record constructor is used to define modified elements. Note, a record constructor must return a complete record, and therefore all elements of the record must have a value (either defined in the constructor or the default values from the class).

The second element `simOpts` is defined without a default value or a binding equation. When instantiating it in the “correct” code, a modifier to its elements is given. In this case, not all elements must be modified. In the “wrong” code, a record constructor is used to define modified elements. This would be fine, but element `method` has no default value in the `SimOptions` class, and the record constructor has no input argument for this element, and this is then an error.

Please note that all this is already standard Modelica semantics and holds for standard record declarations, and therefore it shall hold for record declarations in a custom annotation as well. We have just repeated these points for the sake of clarity.

## 4.4 On Inherited Elements

Since models can be inherited, both the superclass and the subclass may define the same custom annotation. Two cases need to be distinguished:

**Case 1:** the additional custom annotation is defined in the **extends clause**, such as:

```

model MyCar
  extends Car(
    pl annotation(OptimSetup.Tuner(
      active=false)),
    annotation(OptimSetup.OptimOptions(
      tolerance=1e-3))
  );

```

It seems natural to handle this case as modifier, if the custom annotation was already defined in one of the superclasses (otherwise, a new custom annotation is introduced). Therefore, the model can contain the same custom annotation on one element at most once, and the semantics is well-defined (the semantics of a Modelica modifier).

**Case 2:** the additional custom annotation is defined as **class annotation**, such as:

```

model MyCar
  extends Car;
  annotation(OptimSetup.OptimOptions(
    tolerance=1e-4));
end MyCar;

```

In this example it is assumed that in model `Car` the element `tolerance` is defined as `1e-3` and in model `MyCar` as `1e-4`. This creates an ambiguity that needs to be resolved. The Modelica built-in annotations use two different semantics: For the “documentation” annotation, all superclass definitions are ignored. For the “Icon” and “Diagram” annotations, the subclass and superclass definitions are applied after each other (so all of them have an effect).

It is hence proposed to support all these forms by allowing that the same class custom annotation can be used in super- and subclasses. The consequence of this is that an annotation may occur several times in a class. A vector of records can be used to represent the multiple occurrences of one annotation in one class. The order of the vector elements thereby corresponds to the order of inheritance. In case of multiple inheritance, the order of the corresponding extends statements is used.

When generating the standardized “output” format of custom annotations in case 2, such definitions can be represented as a vector of records. The target tool that is using this custom annotations has then to decide how to comprise the information contained in all vector elements. In general, useful strategies are:

- Only utilize the latest definition (last element of the vector), and ignoring definitions in superclasses.
- Only utilize the latest definition (last element of the vector), and triggering an error, if equivalent definitions are provided in superclasses (prior elements of the vector).
- Utilizing all definitions by merging them together (following the order of the vector).

## 4.5 Remaining Issues

### 4.5.1 Handling of undefined annotations using parameters

One problem arises from the point that it is often not possible to define a meaningful default value for a custom annotation element. For example, “method” of the optimization options defines the optimization method to be used and this depends on the optimization environment where the model and the custom annotations will be imported. It is therefore not possible to define a meaningful default value. Furthermore, the modeler may decide to not define a value for the method in the custom annotation of the Modelica model. For this reason, not all elements of a custom annotation record needs to have a value when it is actually used in an annotation. If an element, such as “method” is not explicitly set, then it is not present in the annotation and this implicitly means that the target environment has to cope with this undefined value in a target specific way.

This is not an issue as long as custom annotations are specified directly in the textual layer but providing custom annotations in this way is often not convenient for a user. Instead special blocks or models might be defined where all the relevant information of the custom annotation can be defined in a menu. For example, the `OptimOptions` above might be defined as a partial model that is used via inheritance:

```
partial model OptimOptions
  OptimSetup.OptimOptions optimOptions
  annotation(Placement(...));
  annotation(OptimSetup.OptimOptions(
    method = optimOptions.method,
    tolerance = optimOptions.tolerance),
    Diagram(...);
end OptimOptions;

model DrumBoiler // shall be optimized
  extends OptimOptions;
  ...
end DrumBoiler;
```

In the diagram layer of `DrumBoiler`, the `optimOptions` are present with a record icon:

and clicking on this icon opens a convenient parameter menu for the definition of the options:

method	<input type="text"/>	Optional optimizer method
tolerance	<input type="text" value="0.001"/>	Tolerance of optimization

This approach is welcomed by the user, but currently involves one severe drawback: the user has to provide a value also for optional elements, such as `method`, because this element is propagated to the annotation (above: `OptimSetup.OptimOptions (method = optimOptions.method)`). If no value would be provided, then the translator needs to trigger an error. Therefore, the user can no longer express to not define such an optional custom annotation.

For this reason, it is considered to introduce a limited form of “undefined” handling of definitions and modifiers that is handled during the translation process. The goal is

- to remove annotations if they are defined with “undefined” elements.
- to remove modifications performed in a lower hierarchical level.

So far several approaches to this problem have been suggested but a sufficient level of maturity has yet to be reached.

### 4.5.2 Restricting the application of annotations to certain types

In the current proposal, any annotation might be applied to anything. Also meaningless applications are allowed. For instance the annotation for an optimization tuner cannot only be applied to real numbered parameters but also to Boolean parameters or strings. Even an application to a model class is allowed. Also the annotation for the simulation setup cannot only be applied to model classes as originally intended but also to individual components or variables where it becomes meaningless.

Taken for themselves, such meaningless or ill-applied annotations are not harmful since the meta-data cannot corrupt the main code but yet it might be better to restrict the applicability to annotation to give a better guidance where an annotation is supposed to be used.

How such a restriction is best imposed or if it shall be imposed at all, is still open for discussion. One way of doing it, could be to express the restriction by

annotations themselves in the corresponding annotation record. A new built-in annotation `AnnotationTarget` could serve this purpose. It would contain an enumeration listing for the various possibilities where an annotation can be applied:

```
record AnnotationTarget
  type Target = Enumeration(
    Any,
    ClassDefinition,
    ModelDefinition,
    BlockDefinition,
    ConnectorDefinition,
    RecordDefinition,
    FunctionDefinition,
    TypeDefinition,
    ComponentDeclaration,
    ModelDeclaration,
    BlockDeclaration,
    ConnectorDeclaration,
    RecordDeclaration,
    FunctionDeclaration,
    TypeDeclaration,
    SimpleComponentDeclaration,
    RealDeclaration,
    IntegerDeclaration,
    BooleanDeclaration,
    StringDeclaration,
    InitialEquationAndAlgorithm,
    InitialEquation,
    InitialAlgorithm,
    EquationAndAlgorithm,
    Equation,
    Algorithm,
    ConnectorEquation
  );

  type Prefix = Enumeration(
    Any, None, Constant, Parameter,
    Discrete, Input, Output, Inner,
    Outer, Flow, Stream);

  Target target[:] = {Target.Any};
  Prefix prefix[:] = {Prefix.Any};
end AnnotationTarget;
```

One can now use such an annotation to restrict the applicability of the `Tuner` annotation:

```
record Tuner "Parameter to be optimized"
  import A = AnnotationTarget;
  parameter Boolean active = true;
  parameter Real min;
  parameter Real max;
  annotation(AnnotationTarget(
    target = {A.Target.RealDeclaration},
    prefix = {A.Prefix.Constant,
              A.Prefix.Parameter}
  ));
end Tuner;
```

This definition states, that the `Tuner` record is only to be used in an annotation on a `Real` declaration that has a constant or parameter prefix.

## 4.6 Summary

In this proposal we reuse and generalize existing concepts from the Modelica language. By doing so, we enable the handling of custom annotations. Let us recapitulate our proposed extensions to the Modelica language:

- Regular Modelica records can be used within annotations.
- Custom annotations can be applied in hierarchical modifiers.
- Hierarchical records are automatically supported in annotations.

For the moment, custom annotations are regarded as an additional feature but for the longer-term future an even extended concept shall be used to define also the standardized annotations. This would unify the language and reduce the complexity of the specification.

## 5 Using Meta-Information

In the previous section it was proposed how to store meta-information in a Modelica model. Due to its definition, it is not allowed to use this information in the model itself. The question is how a user or a tool can inquire the stored meta-information. Of course, if meta-information is related closely to a simulation model, most likely the respective Modelica translator has to extract and use the information in a tool specific way (for example meta-information related to the graphical representation of the model in the tool).

In this section, we analyze how to extract and utilize user-defined custom annotations for two possible applications: storing meta-information in FMI format and using meta-information in scripting. Of course many further applications are possible.

### 5.1 Storing Meta-Information in FMI Format

The Functional Mockup Interface (FMI) (*Blochowitz et.al., 2011 and 2012*) is a tool independent standard to support both model exchange and co-simulation of dynamic models using a combination of XML-files and compiled C-code. For details see, <https://www.fmi-standard.org/>. Most Modelica tools support the export and import of models in FMI format. The FMI standard stores all static model information in a file called `modelDescription.xml` in XML format. In particular, the information of all exposed variables are stored here, such as name, data type, unit, description text, variability, causality, etc. The FMI format 1.0 has been published in 2010 and

is supported by more as 40 tools. The release candidate of FMI 2.0 has been published in October 2013.

Since custom annotation variables are basically standard Modelica variables with all the attributes of Modelica variables, it is proposed to just store them as standard FMI variables and mark the “custom annotation” property in the name. In particular, the name of a custom annotation variable shall be:

```
<ComponentName>.annotation.<Custom
AnnotationFullClassName>.<elementName>
```

Note, “annotation” is a reserved keyword in Modelica and therefore a name with “.annotation.” cannot be used as component name, so that a name clash between standard Modelica variable names and custom annotation variable names cannot occur.

As previously mentioned, via inheritance the same custom annotation can be used several times in a class annotation. This is handled by always defining a class annotation with a vector name where the index defines the inheritance order (the post-processing tool has then to define how to handle such vectors, e.g., to only use the first one, or utilize all definitions):

```
<ComponentName>.annotation[<i>].<Custom
AnnotationFullClassName>.<elementName>
```

### Example:

The custom annotation proposal has been partially implemented in a Dymola prototype for evaluation. The Modelica model

```
model Vehicle
  parameter Real p1=2 annotation(
    OptimSetup.Tuner(min=-2));
  ...
end Vehicle;

model ControlledDrive
  Vehicle car;
  ...
  annotation(OptimSetup.OptimOptions(
    tolerance=1e-3));
end ControlledDrive;
```

is stored in the following way in modelDescription.xml file with the Dymola prototype:

```
<?XML version="1.0" encoding="UTF-8"?>
<fmiModelDescription
  fmiVersion="2.0"
  modelName="ControlledDrive"
  ...
>

...

<ModelVariables>
  <ScalarVariable
    name="car.p1"
    valueReference=" 16777216"
    description = "..."
```

```
    causality      ="parameter"
    variability    ="fixed">
  <Real start      ="2"/>
</ScalarVariable>

<ScalarVariable
  name="car.p1.annotation.
    OptimSetup.Tuner.min"
  valueReference="0"
  variability    ="constant">
  <Boolean start= "true" />
</ScalarVariable>

<ScalarVariable
  name="annotation[1].OptimSetup.
    OptimOptions.tolerance"
  valueReference="0"
  variability    ="constant">
  <Real start="1.0e-3" />
</ScalarVariable>
...
</ModelVariables>
</fmiModelDescription>
```

The “annotation” in a name uniquely identifies the component to which this annotation is associated. For example “car.p1.annotation...” means that this variable is a custom annotation to variable “car.p1”. Usually, custom annotation variables are constants or parameters that are **evaluated** during translation and therefore these variables are stored with variability=“constant” and with a literal value in the xml file.

However, the above scheme is not restricted to this case: A custom annotation may contain time varying variables. In such a case the XML file alone is not sufficient to store the information, but a full FMU (Functional Mockup Unit) is needed, because the code to compute a time-varying variable at a particular time instant needs to be evaluated by the compiled C-code of the FMU.

If a tool already supports the export of a Modelica model in FMI format, then custom annotation variables have just to be included and stored in the standard variable tree.

## 5.2 Using Meta-Information in Scripting Environments

Typically, user-defined custom annotations are used to setup special analysis or synthesis environments, like optimization, nonlinear model predictive control, Monte Carlo simulation or uncertainty analysis. For this, the underlying model is needed, as well as the analysis-specific custom annotations defined in the model. If the custom annotations are stored in FMI format as proposed in the previous sub-section, the further processing is, in principal, simple: The information is stored in an XML-file and there are many scripting environments available, such as Java,

JavaScript, Matlab, Python, Ruby, to very easily read XML files and deduce the desired information from it. Therefore, meta-information about non time-varying custom annotations can be deduced in a straightforward way from all these scripting environments. If also time varying variables shall be supported, a scripting environment with FMI support is needed. Typically, the scripting environment will be used, in which the analysis or synthesis task can be directly formulated.

When using Dymola (Dassault Systèmes, 2014), there are scripts available to perform offline and online optimization, Monte Carlo simulation, calibration and others. It is natural to simplify the setup of these tasks by defining the model specific parts already in the respective model using custom annotations. Dymola uses the algorithmic part of Modelica as scripting language. Unfortunately, there is no API available to read XML files. This might also be not possible in a generic way, because the data structures supported by Modelica are not powerful enough for such applications.

For this reason, a special new Dymola API function was designed and implemented to read the variable information of an FMI 2.0 XML file (so the information about all exposed signals). The approach is demonstrated in the following code fragments:

```
function generateXXXsetup
  input String fileName;
protected
  ScalarVariable scalarVariable[:] =
    importScalarVariables(fileName);
algorithm
  ...
end generateXXXsetup
```

Function `generateXXXsetup` is a user-defined Modelica function to read an FMI XML file and generate the setup for the respective analysis task. The core is the new Dymola API function `importScalarVariables` that reads the `<ScalarVariable>` part of an FMI XML file and from this information all custom annotations can be deduced. The function returns a vector of records that has a complicated structure: Since Modelica does not have variant records, the different parts of the variable description are just appended. Some parts of the record definition are given below:

```
record ScalarVariable
  import Records.InternalRecords.*;
  import Records.Enumerations.*;
  String      name;
  Integer     valueReference;
  Causality   causality;
  Variability  variability;
  Initial     initialDefinition;
  OptionalInteger previous;
```

```
  Type        variableType;
  RealAttributes realAttributes;
  IntegerAttributes integerAttributes;
  BooleanAttributes booleanAttributes;
  StringAttributes stringAttributes;
  IntegerAttributes enumerationAttributes;
end ScalarVariable;

record RealAttributes
  OptionalString declaredType;
  OptionalString quantity;
  OptionalString unit;
  OptionalString displayUnit;
  OptionalReal min;
  OptionalReal max;
  Real nominal;
  Boolean unbounded;
  OptionalReal start;
  OptionalInteger derivative;
  OptionalBoolean reinit;
end RealAttributes;

record OptionalReal
  Boolean present;
  Real Value;
end OptionalReal;
...

```

Many attributes of `<ScalarVariable>` are optional. There is no special data type in Modelica to support optional values. For this reason, records “OptionalXXX” are used: Boolean element `present` defines whether the `Value` is defined, or was not given.

By inspecting all “`scalarVariable[i].name`” strings that have `.annotation.` in their name, the desired custom annotations can be deduced and can be utilized to generate the desired default setup of the respective environment.

## 6 Conclusions

There is a strong need to deal with meta-information in equation-based languages. We presented here a first design in order to enable a better handling of meta-information in Modelica: *custom annotations*.

These can be defined by the user and can be organized within packages. For the long term future, we hope to extend this concept to such a degree that a very high percentage of existing annotations can be covered by one unified concept and the specification can be simplified accordingly. For the near future, we are confident that the proposal will be the base for an enhancement of the Modelica language specification.

It is important to note that the presented design is a design proposal and by no means a definitive design. Also the Modelica Association offers a new process called Modelica Change Proposal (MCP) to

work a proposal into the language specification. The desired design for custom annotations will undergo this process and thereby being reviewed and eventually improved. The aim of this publication is hence to inform the public about the ongoing efforts for handling meta-information in Modelica and not to announce a definitive design decision.

## Acknowledgements

The custom annotation proposal in this article was developed within the ITEA2 project MODRIO. Partial financial support of the German BMBF and the Swedish VINNOVA for this development are highly appreciated.

This development was initiated by the MORIO project leader Daniel Bouskela, because associating meta-information with a Modelica model is a core feature needed in the MODRIO project.

Several variants of this proposal have been discussed in Modelica Design Meetings and via the Modelica trac system. Comments and improvement suggestions, especially from (alphabetical list): Volker Beuter, Peter Fritzson, Hans Olsson, Jesper Mattsson, Martin Sjölund, Michael Tiller, are highly appreciated.

A Dymola prototype to export custom annotations in an FMU was implemented by Hans Olsson and Karl Wernersson. Based on this prototype, Hans Olsson proposed to simplify the name lookup as it is described now in this paper.

The Dymola API function to read the variable description from an XML-file into Modelica was implemented in a prototype by Karl Wernersson. Based on this prototype, he proposed to refine the design, especially with respect to undefined attributes.

Custom annotations are already utilized in project MODRIO to develop optimization setups of various optimization problems. This work, carried out by Bernhard Bachmann, Martin Otter, Andreas Pfeiffer and Vitalij Ruge, gave valuable hints for the design of this custom annotation proposal.

## Abstract

This paper describes a proposal for modeling systems with multiple operating modes, such as changing a controller from nominal operation to startup or shutdown or describing failure situations where the model structure is changing (e.g. an electrical line or a mechanical shaft breaks). This is achieved by extending the Modelica 3.3 synchronous state machines to continuous-time state machines having continuous-time models as “states”. Every model can be a “state” of a state machine, and in particular certain acausal models. Currently, no new language element is needed for Modelica, but a generalized semantics for state machines has to be introduced, such as “merge semantics for differential equations”. Symbolic transformations are still handled during translation, so the generated code is efficient and there is no run-time interpreter. On the other, this feature restricts the class of multi-mode systems that can be handled.

*Keywords: Multi-mode, failure simulation, dynamically changing states, continuous-time state machine, hybrid state machine.*

## 1 Introduction

The intention is to extend the scope of Modelica and model and simulate systems with multiple operating modes<sup>1</sup>. Examples:

- Changing a controller from nominal operation to startup, shutdown or manual operation.
- Structural changes of a physical model (e.g. modeling the separation mechanism of a two or three stage rocket).
- Describing failure situations where the model structure is changing (e.g. an electrical line or a mechanical shaft breaks).

- Describing failure situations where the model is completely changing (e.g. the normal behavior of a pump is a 0D model. In case of cavitation, a 1D model is needed to describe physics, requiring to switch dynamically from a 0D to a 1D model when cavitation occurs).

In general this means that the number of continuous-time states of the model might change dynamically during the simulation. Such models cannot be described with current Modelica, version 3.3 (*Modelica Association, 2012*), since in this case the basic requirement is that the number of continuous-time states of a model is fixed during a simulation.

The basic idea for multi-mode modeling is to extend the Modelica 3.3 synchronous state machines (*Elmqvist et. al., 2012*) to continuous-time state machines having continuous-time models as “states”. Every model can be a “state” of a state machine, including acausal models, such as a capacitor, or a rotational inertia. The number of continuous-time state variables can change at a transition of a state machine. No new Modelica language element is needed, but a generalized semantics for state machines has to be introduced, such as “merge semantics for differential equations”. The concepts have been evaluated with a Dymola prototype (*Dassault Systèmes, 2014*).

A related paper (*Bouissou et. al., 2014*) discusses the use of continuous-time state machines in Modelica for the modeling of stochastic hybrid systems by means of Piecewise Deterministic Markov Processes (PDMP). It focuses on how to handle the case when the transitions on continuous-time state machines depend on stochastic transitions.

Modeling state machines with differential equations in the states is a well-known approach in automata theory, called hybrid automata, see e.g. (*Henzinger 1996*). Such an approach is only of limited use when modeling physical systems, even if the Ordinary Differential Equations (ODEs) on a state are extended to Differential-Algebraic Equations (DAEs): The user has to enumerate all different configurations of a system and has to provide the equa-

<sup>1</sup> Section 1 and 2 of this article are an updated version of the internal report D4.1.2-M12 from the ITEA2 project MODRIO. The rest of this article is new material.

tions for every configuration and also provide all the details to switch between these configurations, see also next section.

MOSILAB (Bastian et al., 2010) from Fraunhofer is an extension to Modelica by introducing continuous-time statecharts in Modelica and supporting DAEs on the states. This approach has similar drawbacks as hybrid automata, but is more powerful as hybrid automata due to the usage of Modelica.

Sol (Zimmer, 2010) is an experimental language to model variable structure systems with index changes. The large flexibility requires an interpreter for the simulation: Whenever the DAE index of a system is changed during simulation, the relevant equations of the model are newly symbolically processed and especially also newly index-reduced. The advantage is that a very large class of physical systems with variable structure can be described. The drawback is that an interpreter is needed at run-time, considerably reducing the simulation efficiency.

The approach presented in this paper introduces certain restrictions on what kind of changes can be made to the model at a mode change. This allows symbolic transformations still to be handled during translation, so the generated code is efficient and there is no run-time interpreter.

## 2 Continuous-time state machines with causal blocks

### 2.1 Synchronous state machines

In Modelica 3.3 (Modelica Association, 2012) synchronous state machines are defined. These state machines are only executed as sampled data systems. From the specification:

*Any Modelica block instance without continuous-time equations or algorithms can potentially be a state of a state machine. A cluster of instances which are coupled by transition statements makes a state machine. All parts of a state machine must have the same clock. All transitions leaving one state must have different priorities. One and only one instance in each state machine must be marked as initial by appearing in an initialState statement.*

### 2.2 Continuous-time state machines

In order to define multi-mode systems, the basic idea is to generalize the clocked state-machines from Modelica 3.3 to continuous-time. In a first step, two cases are distinguished:

1. All states and transitions of one state machine are clocked and belong to the same clock (= semantics in Modelica 3.3).
2. All states and transitions of one state machine are continuous-time (= new, additional semantics; discussed below).

In this section we only consider “causal” continuous-time systems, that is, the “states” must be “blocks” with defined “input” and “output” variables. As a result, every “state” block can be separately symbolically processed (such as BLT partitioning) assuming that all its inputs, `pre( . )` and arguments of `der( . )` are known and all other variables, especially outputs, `der( . )`, and arguments of `pre( . )` are unknown. Therefore, from a conceptual point of view a “state” is a set of ordinary differential equations (ODE) with known inputs  $\mathbf{u}$  and states  $\mathbf{x}$  and of explicit algebraic equations with unknown outputs  $\mathbf{y}$  computed in the block:

$$\begin{aligned}\dot{\mathbf{x}} &= \mathbf{f}(\mathbf{x}, \mathbf{u}, t) \\ \mathbf{y} &= \mathbf{g}(\mathbf{x}, \mathbf{u}, t)\end{aligned}$$

The outgoing transitions of the active state of a state machine are Boolean conditions that are continuously monitored and are transformed to event indicator signals (also called zero-crossing functions) that signal an event when the Boolean condition changes its value. At this time instant the numerical integration is stopped, the state machine switches to the new “state” and the ODE of this new state is either restarted or continues from the previous value of its continuous-time state variables when the “state” was active the last time.

As a simple example consider the continuous-time state machine in Figure 1 with two “states”. This state machine consists of “states” that consist of completely unrelated blocks (in the upper “state” it is a drive train with clutches, and in the lower “state” it is a controlled electrical motor with load). At the start of the simulation the upper state is active and the drive train is simulated. At time = 1.5 s, the simulation of the drive train is stopped and the controlled electrical motor block starts simulating.

As can be seen, the number of continuous-time states changes dynamically during simulation and the state machine switches between unrelated models. There is the restriction that every “state” block needs to have a full initialization definition (e.g., starting from given start values of the continuous-time states, or starting from a steady-state condition which requires to solve a nonlinear algebraic equation system when the block becomes active the first time). When a “state” block is activated the first time, the initialization equations are first evaluated before the simu-

lation of the block is started. When a “state” block is re-entered, the block is re-initialized if the reset flag is set in the transition. Otherwise, the block continues from the values of the continuous-time variables state of the previous activation.

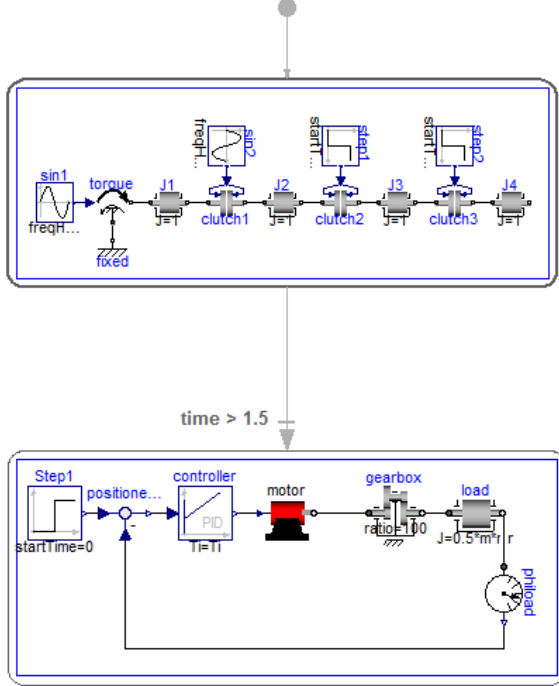

Figure 1: Continuous-time state machine

### 2.3 Hybrid automata

The system in Figure 1 is practically not very useful, since signal values are not exchanged between the different “state” blocks. More useful state machines are the already mentioned hybrid automata, see for example (Henzinger 1996). A simple example is shown in Figure 2 and Figure 3:

Figure 2: Hybrid automata with “a” as input signal.

On every “state” an ODE is present. The transition conditions consist of trigger conditions when to switch the state (e.g. “[ $x \geq 3$ ]”). Furthermore, at the transition it is defined in which way to reset the state of the ODE (e.g. “/ $x:=1$ ” means that continuous-time state  $x$  is reset to 1, before entering the target “state”). In the Dymola prototype, this state

Figure 3: Solution of the hybrid automata from Figure 1 with  $a = \text{time} > 2.5$ .

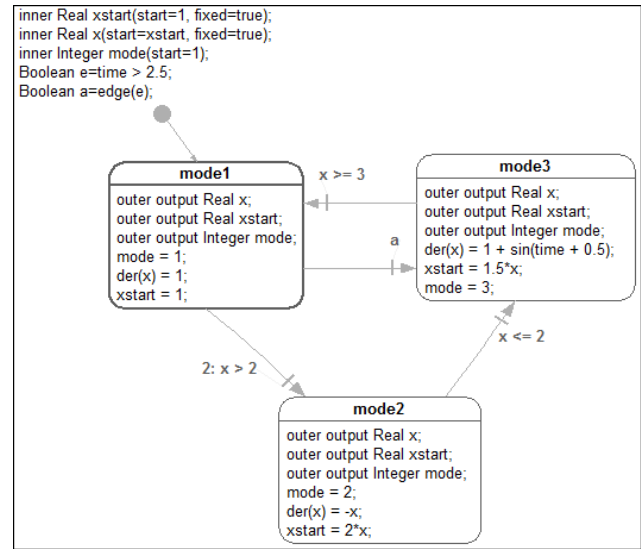

Figure 4: Hybrid automata from Figure 1 modeled in Modelica with indirect reset.

machine can be modeled with the proposed Modelica extension according to Figure 4. Here, every “state” is a block that contains the differential equation. Note, the same continuous-time state variable “ $x$ ” is used in all “states” (called “mode1”, “mode2”, “mode3” here), because this variable is defined with “outer output” in the mode blocks. Additionally, the start value  $xstart$  of the state is reported via inner/outer to all mode blocks. The expected semantics is that whenever entering a “state” and the reset flag in the transition is set, then the differential equation is newly initialized with the actual start value of “ $x$ ”.

The current semantics of the prototype implementation in Dymola is that when an immediate transition is used, the equations are activated once before the reset is made. This explains why  $xstart$  is modified in the destination state. The use of the construct:

```
inner Real xstart(start=1, fixed=true);
inner Real x(start=xstart, fixed=true);
```

is not standard Modelica since the variability of the start attribute is parametric. To allow any variability of the start expression would be one possible extension to Modelica to solve the re-initialization problem. However, the solution of using a “global” variable `xstart` is not elegant and is error prone. It would be better to allow such information for re-initialization to be associated with the transition. Further investigations are needed for designing the “right” extension.

Similarly as for clocked synchronous state machines, also for continuous-time state machines the “single assignment rule” holds for every variable. This means that variables in the different “states” must be merged. The merge-semantics for algebraic variables is identical to the merge-semantics of clocked synchronous state machines (see section 17.3.5 of the Modelica 3.3 specification). Variables that appear in the derivative operator, `der(..)`, are merged in the following, equivalent way:

```
der(x) := if activeState(state1) then
  expr1
elseif activeState(state2) then
  expr2
elseif
  ...
else last(der(x))
```

This means that in the example above, the equations for `der(x)` in the different “state” blocks are merged into the following single statement:

```
der(x) := if activeState(mode1) then
  1
elseif activeState(mode2) then
  -x
elseif activeState(mode3) then
  1 + sin(time+0.5)
else last(der(x))
```

### 3 Continuous-time state machines with acausal models

Hybrid automata are of limited use for physical system modeling, because the equations have to be first manually transformed into an input-output block and this is inconvenient and might be non-trivial. Furthermore, the graphical representation in an object diagram might be “not nice” due to input and output connections in a diagram that uses physical, that is acausal, connectors otherwise. Therefore, from a user point of view, it is important to support acausal models as “states”. In general this is non-trivial, because different “states” may require different symbolic handling of the equations in the environment since causality and the DAE index might change between “states” of a state machine. However, a quite

large class of acausal model “states” have been identified that can be reasonably handled.

As an example, consider the electrical circuit with two state machines in *Figure 6*. In the upper part of the electrical circuit a diode model is present as a “state”. At “time > 0.9” this state is left and state “brokenDiode” is activated consisting of a resistor with a large resistance. Note, that the “states” have “electrical pins” from which they are connected with the rest of the circuit. In the lower right part of the circuit diagram, another state machine is present. It consists of a capacitor “state” (modeled as a resistor in series with an ideal capacitor model).

At time = 0.3s, the hardware configuration is changed and the state switches to state “R2” consisting of a small resistance. At time 0.7s, the configuration is switched back. Note, that in this second case the number of continuous-time states is changing when switching.

In the rest of this section, the new method is described that allows us to handle such systems in an efficient way.

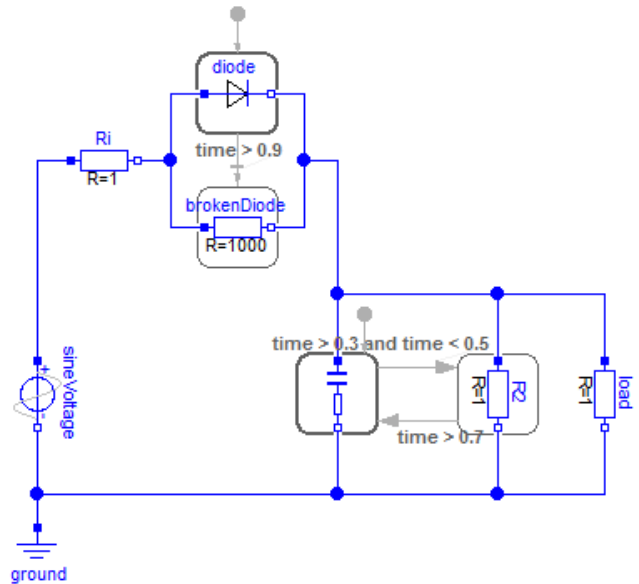

Figure 5: Circuit with two acausal state machines.

Figure 6: Simulation result of the circuit of Figure 5.

### 3.1 Basic idea for symbolic processing

The basic idea to symbolically process continuous-time state machines with physical connectors is explained at hand of the simple example in *Figure 7*. This circuit contains a state machine with two states, capacitor  $C$  (state 1) and resistor  $R_2$  (state 2). The simulation starts with capacitor  $C$  and after 0.5 s the state machine is switched to the resistor  $R_2$ . Conceptually, the same behavior can be achieved with the Modelica model shown in *Figure 8* where the models of the two previous two states are connected together with a special switch explained below.

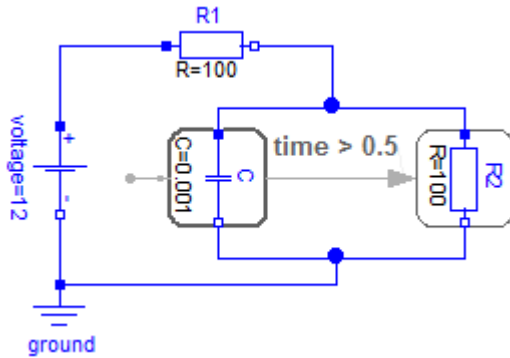

Figure 7: Simple circuit with an acausal state machine.

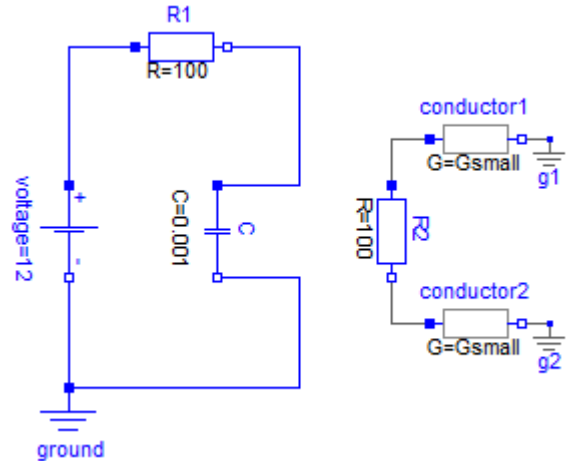

Figure 8: Simple circuit from Figure 7 implemented with special switches using standard Modelica.

Via the Integer input *state* to the switches it can be defined whether pin *n1* or pin *n2* is connected to pin *p*. In the circuit from above, it is defined as:

```
Integer state = if time <= 0.5 then 1
               else 2;
```

The effect of the two switch positions is demonstrated in *Figure 9*. If in state 1, the capacitor  $C$

Configuration if *state* = 1

Configuration if *state* = 2

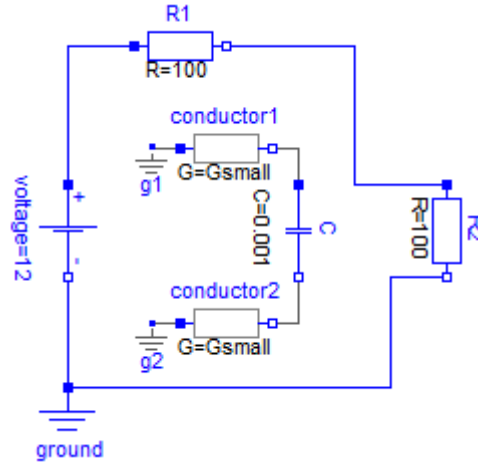

Figure 9: The two configurations of the simple circuit from Figure 8.

is connected with the rest of the circuit. The resistor  $R_2$  is connected with small (dummy) conductances to ground. This is necessary, because otherwise  $R_2$  would be “floating” and there would be missing equations for voltages. The currents into the pins would be zero since no environment would be attached. However, it is already stated in the resistor that the currents sum to zero. So there would be one equation too much for currents.

If in state 2, the resistor  $R_2$  is connected with the rest of the circuit. The capacitor  $C$  is connected with small (dummy) conductances to ground, similarly as the resistor in state 1.

It is clear that both configurations can be simulated with a standard Modelica simulator and that the variables of the “active” state will have identical results to the “active” state of the circuit in *Figure 7*. In order to achieve this behavior, the special switch models of *Figure 8* need to be defined as:

```
// Equation for potential variables
p.v = if state==1 then n1.v else n2.v;

// Equation for flow variables
0 = p.i + (if state==1 then n1.i
           else n2.i);

// Equation for not connected state
0 = if state==1 then Gsmall*n2.v-n2.i
    else Gsmall*n1.v-n1.i;
```

There are different variants to formulate the equations of this switch. The variant above has the advantage that one equation depends only on potential variables, but not on flow variables, and one equation depends only on flow variables and not on potential variables. This is the same principal structure as for every single configuration. For example, assume that in both configurations the potential variable equations need to be differentiated (due to a constraint between states). If in this case the combined potential variable equation of the switch is differentiated, then no flow variables are differentiated because the equation contains only potential variables.

The basic idea to handle acausal state machines can now be sketched:

- (1) Connect statements from the outside of a state machine to connectors on the states of a state machine are replaced by the equations of the special switch statement above.
- (2) All state machine states are removed and the equations of all states and all transitions are added to the rest of the model. The result is a standard DAE according to current Modelica.
- (3) The standard symbolic transformation algorithms are applied on this resulting DAE, such as Pandelides algorithm (*Pandelides 1988*), BLT, dummy derivative method (*Mattsson and Söderlind 1993*).
- (4) When generating code, all equations originally belonging to a state are de-activated (are not evaluated), when this state is not active. Furthermore, all continuous-time state variables from all non-active states are removed from the integrator<sup>2</sup>.

Note, applying rules (1) and (2) on the example from *Figure 7* results in the circuit of *Figure 8*. Due to rule (4), the code for the dummy conductors will not be executed and therefore the values of the conductances do not matter. The conductors are only important during the symbolic transformation phase

where structural properties of the equations are utilized.

Since the symbolic processing might differentiate equations and/or might lead to linear or non-linear systems of equations, this means, that also equations on states might be differentiated or algebraic systems of equations over states and non-states might be present.

In the rest of this paper, the above sketch is more formally defined, consequences and limitations are discussed and several examples are presented.

### 3.2 Mapping physical connections to equations

In this section it is defined how the `connect(...)` statement of Modelica is mapped to equations if one of the arguments is a connector on a state of a state machine.

#### 3.2.1 Connections between states of one state machine

##### Requirement 1:

It is not allowed to have a connection set where all connectors of the set belong to the same state machine and at least two connectors are on different states of this state machine.

Note, the states of a state machine are mutually exclusive. If there are connections between mutually exclusive states of a state machine, then the connection will never have an effect (because always only one connector will be active), and there will be missing equations.

#### 3.2.2 Connections between single potential-flow variable pairs

Assume a connector  $c_i$  present on a state  $i$  is defined by one potential variable  $p_i$  and one flow variable  $f_i$  and that  $n$  of these connectors from the same state machine are connected to connectors outside of this state machine.

A virtual connection node  $c_0$  is (conceptually) introduced outside of the state machine. All connections from  $c_i$  to connectors outside of the state machine are replaced by connections to  $c_0$  and connections from  $c_0$  to the original targets. As a result, the following connect statements will be present (the connect statements to the targets are handled according to current Modelica):

```
connect(c0, c1)
connect(c0, c2)
...
connect(c0, cn)
```

<sup>2</sup> A simple way to not integrate over deactivated states is to just report to the integrator that the derivatives of these states are zero, and otherwise keep the dimension of the state vector.

These connect statements are replaced by the following equations, where  $i$  characterizes the active state:

**Mapping Equations 1:**

$$\begin{aligned} \mathbf{p} &= [p_1, p_2, \dots, p_n]^T \\ \mathbf{f} &= [f_1, f_2, \dots, f_n]^T \\ i &= \text{activeState}() \end{aligned}$$

$$\begin{aligned} p_0 &= \mathbf{p}[i] \\ 0 &= f_0 + \mathbf{f}[i] \\ \text{for } j &= 1:n-1 \\ k &= \text{mod}(i+j-1, n) + 1 \\ 0 &= G_{\text{small}} \cdot \mathbf{p}[k] - \mathbf{f}[k] \end{aligned}$$

Note, the for-loop generates  $n - 1$  dummy equations describing a linear relationship between the potential and flow variables of the connectors on the states that are not active. Due to this mapping, the connect equations have the following structural dependency:

$$\begin{aligned} 0 &= g_1(p_0, \mathbf{p}, i) \\ 0 &= g_2(f_0, \mathbf{f}, i) \\ 0 &= \mathbf{g}_{3:n+1}(\mathbf{p}, \mathbf{f}, i) \end{aligned}$$

These are  $n + 1$  equations for  $n + 1$  connectors, where

- one equation depends on all potential variables of the connection set and on the active state,
- one equations depends on all flow variables of the connection set and on the active state,
- $n - 1$  equations depend on all potential and all flow variables of the connectors that are on the state machine and on the active state.

The equations  $\mathbf{g}_{3:n+1}$  are in principal only relevant for the symbolic analysis. During simulation, these equations are never evaluated, because they are deactivated for the active state.

If these equations appear in an algebraic loop, a simple implementation might just compute the solution without taking into account that the equations are deactivated and then ignore the computed value for the deactivated variables. In this case the value of  $G_{\text{small}}$  matters because the value is used during the solution of the equation system, and if the value becomes too small, the Jacobian of the equation system may become badly conditioned. In this case  $G_{\text{small}}$  should be in the order of the other elements of the equation Jacobian (or if this information is not known,  $G_{\text{small}} = 1$  might be used).

An efficient implementation requires to rewrite algebraic equation systems when a new state becomes active. For example, assume a linear system of equations is present during simulation and for state  $i = 1$  it has the form:

$$\begin{bmatrix} \mathbf{A}_{11} & \mathbf{A}_{12} & \mathbf{A}_{13} & \mathbf{A}_{14} \\ \mathbf{0}^T & G_{\text{small}} & -1 & \mathbf{0}^T \\ \mathbf{A}_{31} & \mathbf{A}_{32} & \mathbf{A}_{33} & \mathbf{A}_{34} \end{bmatrix} \cdot \begin{bmatrix} \mathbf{z}_1 \\ p_2 \\ f_2 \\ \mathbf{z}_3 \end{bmatrix} = \begin{bmatrix} \dots \\ \dots \\ \dots \end{bmatrix}$$

Since the variables and equations of state  $i = 2$ , especially  $p_2, f_2$ , are deactivated (and the variables hold their values) if this state is not active, this linear system of equation can be simplified for state  $i = 1$  to:

$$\begin{bmatrix} \mathbf{A}_{11} & \mathbf{A}_{14} \\ \mathbf{A}_{31} & \mathbf{A}_{34} \end{bmatrix} \cdot \begin{bmatrix} \mathbf{z}_1 \\ \mathbf{z}_3 \end{bmatrix} = \begin{bmatrix} \dots \\ \dots \end{bmatrix}$$

With this type of equation handling,  $\mathbf{g}_{3:n+1}$  are never evaluated during simulation and the value for  $G_{\text{small}}$  does not matter.

Note, when implementing a generic switch for  $n$  connectors, the “Mapping Equations 1” can be compactly defined in Modelica:

```
input Integer state;
parameter Integer nStates;
Pin p, n[nStates]
equation
  p.v = n[state].v;
  0 = p.i + n[state].i;
  zeros(nStates-1) = {Gsmall*
    n[mod(state+i-1, nStates)+1].v -
    n[mod(state+i-1, nStates)+1].i
    for i in 1:nStates-1};
```

### 3.2.3 Connections between input-output connectors

Assume state  $i$  of a state machine is an input-output block with an input  $u_i$  and an output  $y_i$  and that  $n$  of these connectors from the same state machine are connected to connectors outside of this state machine – from a node  $u_0$  to the inputs  $u_i$  and from the outputs  $y_i$  to a node  $y_0$ . This means that the following connect statements are present:

```
connect(u0, u1)          connect(y1, y0)
connect(u0, u2)          connect(y2, y0)
...
connect(u0, un)          connect(yn, y0)
```

These connect statements are replaced by the following equations, where  $i$  characterizes the active state:

**Mapping Equations 2:**

$$\begin{aligned} \mathbf{u} &= [u_1, u_2, \dots, u_n]^T \\ \mathbf{y} &= [y_1, y_2, \dots, y_n]^T \\ \mathbf{u} &= u_0 \cdot \text{ones}(n) \\ y_0 &= \mathbf{y}[\text{activeState}()] \end{aligned}$$

These are  $n + 1$  equations for  $n + 1$  connections. When a state  $j$  is not active, an arbitrary value can be provided for its input  $u_j$ . For simplicity, just the

overall input  $u_0$  is provided, so  $u_j = u_0$ . Again, because equations on not active states are deactivated during simulation, these equations are only present during the symbolic transformation, but not during run-time. Therefore, the actually provided value for the input does not matter. Additionally, to the mapping rules above, the standard input-output semantic restrictions (e.g. an output can be only connected to one input), must be relaxed, so that this rule holds only for the active state, but not for deactivated states.

In Figure 10 an example with two input-output blocks is given: The simulation starts with block `firstOrder`, a first order block. When time > 0.5, the state machine switches to block `secondOrder`. Entering `secondOrder` re-initializes the block to the output of state `firstOrder` (more details on re-initialization are given in section 3.3).

Figure 10: State machine switching between two input-output blocks.

Simulation results are shown in Figure 11. Here a first order behavior is seen for the first 0.5 s. Afterwards a second order behavior occurs.

Figure 11: Simulation results of the state machine of Figure 10.

### 3.2.4 Equation rewriting to enhance efficiency

The approach from section 3.2.2 might lead to algebraic equation systems where the size of the systems is unnecessarily large. In some cases these sizes might be reduced with the following rewriting rules for connect equations:

First, run the Pantelides algorithm (Pantelides 1988) and perform the BLT (Block Lower Triangular) transformation on the differentiated problem.

Second, if the following equations of one connection set (see “Mapping Equations 1”),

$$\begin{aligned} p_0 &= p[i] \\ 0 &= G_{small} \cdot p[k] - f[k] \end{aligned}$$

or their differentiated form, appear in an algebraic equation system having all potential variables  $p[k]$  as unknowns, but not the flow variables  $f[k]$ <sup>3</sup>, then the equations above can be reformulated to:

for  $i = 1:n$   
 $p[i] = \text{if activeState}(i) \text{ then } p_0 \text{ else last}(p[i])$

where  $\text{last}(p[i])$  is the value of  $p[i]$  when state  $i$  was active the last time (so it is a known value).

The proof for this rewriting is given for  $n = 2$ . For  $n > 2$ , similar arguments can be given. So, assume  $n = 2$ . Then, the equations from the connect-statements have the following form for the different states, according to “Mapping Equations 1”:

```

if activeState(1) then
     $p_0 = p_1$ 
     $0 = f_0 + f_1$ 
     $0 = G_{small} \cdot p_2 - f_2$ 
else
     $p_0 = p_2$ 
     $0 = f_0 + f_2$ 
     $0 = G_{small} \cdot p_1 - f_1$ 
end if
    
```

Since it is assumed that the flow variables  $f_1$  and  $f_2$  are known (are computed somewhere else), the dummy conduction equations can be solved for the potential variables (e.g.  $p_2 := f_2 / G_{small}$ ). This means that for the non-active states, the potential variables are known. Instead of computing them by a dummy conduction equation, alternatively another known value can be used (because all equations of non-active states are anyway de-activated) and especially  $\text{last}(p[i])$ . As a result, the equations above are equivalent to:

<sup>3</sup> The flow variables do not appear in the algebraic loop if all are continuous-time states or are computed from continuous-time states.

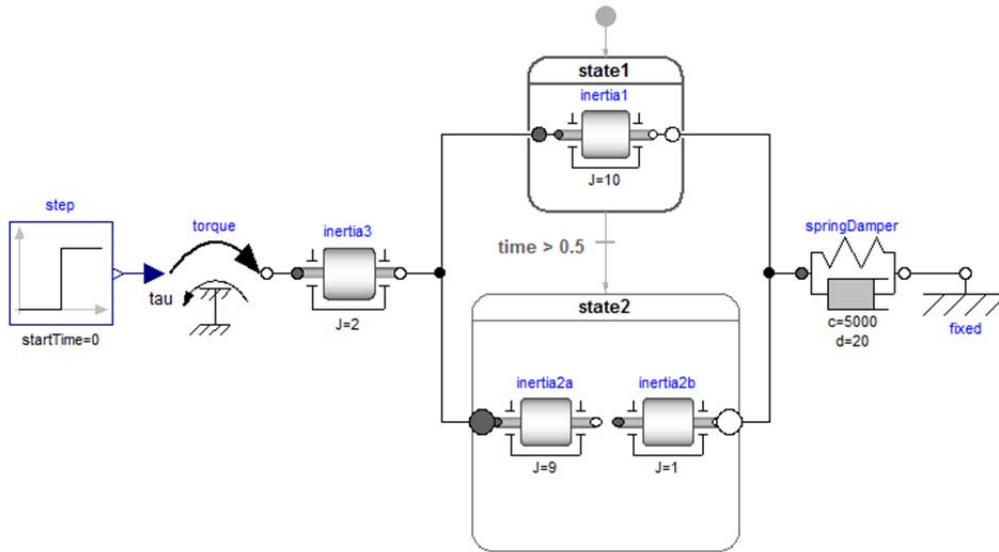

Figure 12: Breaking inertia that requires index reduction and algebraic loop handling over a state machine, as well as re-initialization when entering state2.

if activeState(1) then

$$p_0 = p_1$$

$$0 = f_0 + f_1$$

$$p_2 = \text{last}(p_2)$$

else

$$p_0 = p_2$$

$$0 = f_0 + f_2$$

$$p_1 = \text{last}(p_1)$$

end if

This equation set is in turn equivalent to:

$$p_1 = \text{if activeState(1) then } p_0 \text{ else last}(p_1)$$

$$p_2 = \text{if activeState(2) then } p_0 \text{ else last}(p_2)$$

$$0 = f_0 + \text{if activeState(1) then } f_1 \text{ else } f_2$$

and the proof is complete.

After re-writing the equations, all symbolic algorithms are re-run. Usually, the equation systems will become smaller, since the equations depend now only on two variables, and not on many variables. Intuitively this rewriting means that  $p_0$  is computed outside of the state machine and propagated to the states of the state machine. Therefore, the previous algebraic loop over all the states is broken. A prerequisite for this rewriting is that for all non-active states it is sufficient to treat the potential variables as inputs. A sufficient condition for this to be possible is that the flow variables have been already computed somewhere else.

In a similar way, the equations can be rewritten, if the flow variable equation and the dummy conductor equations are in an algebraic loop.

### 3.3 Re-Initialization

When changing from one state to another one, the DAE of the target state must usually be initialized. This is basically performed with the methods from section 2.3 as demonstrated at hand of the example in Figure 12. This example models a drive train, where a rotational inertia breaks during the operation. In particular, this models consists of

- a state1 with inertia1 and J=10,
- a state2 with inertia2a (J=9) and inertia2b (J=1) that are not connected,
- an inertia3 outside of the state machine that is connected to inertia1 and inertia2a and is driven by a step torque<sup>4</sup>, and
- a spring-damper that is connected to inertia1 and inertia2b.

At time = 0.5, the state machine switches from state1 to state2 and therefore inertia1 is replaced by two unconnected inertias that have together the same moment of inertia as inertia1. In other words, the “breaking” of inertia1 is modelled. Note, that the number of continuous-time states is changing (there are 2 continuous-time state when in state1 and 4 when in state2).

With the generation of connect equations in section 3.2 and the sketched symbolic processing of the overall DAE, this system gives rise to index reduction between inertia3, inertia1 and inertia2a

<sup>4</sup> inertia3 is only present to demonstrate index reduction and algebraic loops over a state machine

and due to this index reduction an algebraic loop between equations of these components are present. The Dymola prototype handles this correctly.

When switching from `state1` to `state2`, `inertia1` has some angle and angular velocity and the inertias on `state2` need to be appropriately initialized. Since `inertia2a` is rigidly attached to `inertia3`, no initialization of `inertia2a` is needed. However, the continuous-time states of `inertia2b` need to be initialized to the states of `inertia3`. This is performed in the following way:

```
inner Real phi(start=0, fixed=true) =
    inertia3.phi;
inner Real w(start=0, fixed=true) =
    inertia3.w;
...
// in state2
import R=Modelica.Mechanics.Rotational;
outer Real phi;
outer Real w;
R.Components.Inertia inertia2b(J=1,
    phi(start=phi, fixed=true),
    w(start=w, fixed=true));
```

On the top level the inner variables `phi` and `w` are associated with the corresponding variables of `inertia3`. In `state2` these variables are declared as `outer` and used as start values for `inertia2b`. The semantics is that when `state2` is entered, then the variables of `state2` are re-initialized to their start values. A result plot of the angular velocities of the inertias on the two states is shown in *Figure 13*.

Figure 13: Simulation result for the breaking inertia of Figure 12.

As can be seen, the amplitude and frequency of `inertia2b` increases with respect to `inertia1`, because its moment of inertia is much smaller.

### 3.4 Limitations

The question arises which types of models cannot be handled with the proposed approach? First, independently of the symbolic algorithms used, the map-

ping of connect statements to equations as defined in section 3.2 is always correct. It is clear that there must be limitations when applying the standard symbolic algorithms on the resulting set of equations, because the structure of the equations depends on the active state and this dependency is not taken into account by the standard algorithms. For example assume that the following equation is present

```
p.v = if state==1 then n1.v else n2.v
```

when mapping some connect statements to equations. Assume that `p.v` and `n1.v` are states, but `n2.v` is not. Then this state constraint is not detected and `n2.v` is always computed from `p.v` and from `n1`. Of course, this will fail (will give a division by zero) in state 1. The correct handling would be that in state 1 the equation `p.v = n1.v` is present and if both variables are states, this equation must be differentiated. However, the standard algorithms do not take this into account and it seems also non-trivial to generalize.

In *Figure 14* there is a state machine with a capacitor `C1` and a resistor `R2`. These two states are connected in parallel to a capacitor `C2`. This model cannot be handled with the proposed method (and will give a run-time error that a matrix is singular), because in the capacitor state there is a state variable constraint between `C1` and `C2` and in the resistor state there is no such state constraint.

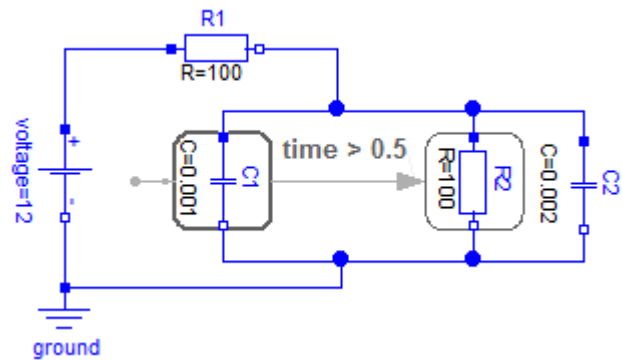

Figure 14: Parallel capacitors that cannot be handled due to different state constraints in the different states.

In *Figure 15* there is a state machine with a connection of two flanges in `state1` and no connection in `state2` (this is defined by connecting zero-torques to the two flanges). This state machine is placed between two inertias. The model describes a breaking inertia in a more natural formulation as in *Figure 12*. This model cannot be handled with the proposed method (and will give a run-time error that a matrix is singular), because in `state1` there is a state constraint between `inertia1` and `inertia2` and in `state2` there is no such state constraint.

Figure 15: Breaking inertia that cannot be handled due to different state constraints in the different states.

It is not nice that such models lead to an error only when simulating the model. It is also difficult to deduce the source of the problem from an error message stating that a matrix is singular. In principal, the diagnostics can be improved, so that such errors occur during translation with an understandable error message:

The sorted equations are inspected and every algebraic equation system that depends on a state of a state machine is processed again: The equations of an algebraic equation system are partitioned (so the assignment algorithm is applied) for every state machine state taking into account the equation structure of the particular state only. If one of the assignments fails, the equation system is structurally singular for the selected state and therefore the model cannot be handled.

## 4 Conclusions

A proposal is presented for modeling variable structure systems with dynamically changing number of states in Modelica by extending the synchronous clocked state machines to continuous-time state machines. With this extension it is straightforward to model hybrid automata. However, hybrid automata are not practical to use for physical system modeling. A novel extension is proposed to use acausal models as states of a state machine. By mapping connections to connectors on a state machine in a particular way on equations, the standard symbolic processing for Modelica models can be applied. This approach allows already handling a large class of useful variable structure systems with dynamically changing sizes of continuous-time states.

Models cannot be handled with this new method, if connections between state and non-state components lead to constraints on continuous-time state

variables that vary for the different state machine states.

The proposal is not yet complete. Especially, mappings for all connector types of Modelica need to be still defined, especially for multi-body and for fluid systems. Additionally, the switching between DAEs may lead to Dirac impulses, if not properly re-initialized (or it must be modelled in a way that impulses occur, due to the underlying approximation of the reality). Furthermore, algebraic equation systems over states need to be analyzed in more detail, especially in combination with the dummy derivative method. It is planned to work on these topics in the near future.

## Abstract

The high abstraction level of equation-based object-oriented languages (EOO) such as Modelica has the drawback that programming and modeling errors are often hard to find. In this paper we present the first integrated debugger for equation-based languages like Modelica, which can combine static and dynamic methods for run-time debugging of equation-based Modelica models during simulations. This builds on and extends previous results from a transformational static equation debugger and a dynamic debugger for the algorithmic subset of Modelica.

*Keywords: Modelica, Debugging, Modeling and Simulation, Transformations, Equations, Algorithmic Code, Runtime Errors, Tracing, Solver Failures*

## 1 Introduction

The advanced development of today's complex products requires integrated environments and equation-based object-oriented declarative (EOO) languages such as Modelica [10][14] for modeling and simulation.

The increased ease of use, the high abstraction, and the expressivity of such languages are very attractive properties. However, the downside of this high-level approach is that understanding the root causes of unexpected behavior and numerical errors of simulation model is very difficult, in particular for users who are not experts in simulation methods.

The main reason of this difficulty the fact that lots of sophisticated symbolic and numerical transformations are applied to the original model in order to eventually obtain the executable simulation code, in which errors and problems do occur. An effective debugging environment should then guide the end user

back and forth through the numerical results and all the performed symbolic transformations of the model, in order to quickly find and correct the causes of errors. This paper presents the integrated debugger of the OpenModelica tool suite, including a graphical user interface integrated with the OpenModelica Connection Editor (OMEdit) GUI. This builds on and extends previous results from a transformational static equation debugger [6][7] and a dynamic debugger [1][3][4] for the algorithmic subset of Modelica.

Despite the fact that debugging environments have been the subject of extensive research and implementation work in the field of computer science, to the best of the authors' knowledge this is the first documented operational debugging environment for equation-based modeling languages supporting dynamic debugging of equation-based mathematical models as well as algorithmic code in an integrated way.

The rest of the paper is structured as follows: The debugging procedure is outlined in Section 2 and the GUI in Section 3. The tracing of equation transformation is discussed in Section 4, while Section 5 discusses the issues of interfacing with the run-time simulation executable. In Section 6, some example models are shown, illustrating how the debugger can help their troubleshooting. Section 7 discusses background and related work, Section 8 states the current implementation status at the time of this writing, and Section 9 concludes the paper.

## 2 Overall Debugging Procedure

The debugger should support three basic scenarios:

- The simulation stops at a certain time step, or during initialization, because of a numerical runtime error;

- A complete simulation run has been performed successfully, but some variables exhibit suspicious or clearly wrong values;
- A breakpoint is inserted to stop the integration either at a certain given value of the time variable, or when some user-supplied condition is triggered. In this case, it should be possible to restart the simulation (and possibly to set a new breakpoint)

The different functionalities of the debugger are specified in more detail in the following sub-sections.

## 2.1 Types of Debugging Activities

We divide the problem of debugging the execution (i.e., the numerical simulation) of an equation-based model into three different areas:

- *Initialization.* Before starting the simulation, consistent initial conditions are computed by solving a set of initial equations. In the following, it is assumed that this is done by using multiple optimization strategies, such as alias variable elimination, BLT partitioning, tearing, etc.
- *Causalization.* It is also assumed that the solution of the differential-algebraic equations over time is obtained by a two-stage strategy. In the casualization stage, the DAEs are solved for the derivatives by using multiple optimization strategies, such as symbolic index reduction as well as the ones previously mentioned.
- *Time integration.* The computed derivatives (and possibly their Jacobian matrix) are then passed to ODE solvers, such as DASSL, Runge-Kutta, Radau, etc., that advance the solution of the system over time

## 2.2 Debugging Initialization and Causalization Problems

For the purpose of debugging, initialization and causalization share a common structure despite using different numerical solvers. They can be represented using a similar GUI. The only difference is that the set of equations and unknowns for initialization is larger than for causalization, as it also includes the state variables and the parameters, as well as the initial equations and parameter-binding equations. Also, the simulation code to solve both problems is usually generated by the Modelica tool itself, so it is fairly straightforward for the tool developers to add all kind of instrumentation to it for debugging purposes.

Variables are matched to the equations that are used to solve them. If an error has occurred while trying to compute a certain variable or a certain set of variables

for strong components in the BLT, the error (e.g., division by zero, logarithm of a negative number, singular linear system of equations, etc.) is reported in the context of the equation as it has been transformed in order to solve it efficiently at run time. Then, it is possible to backtrack step-by-step each stage of the transformations of each equation, up to the original equations in the source code.

This activity can also be carried out in the absence of errors, either when a breakpoint is triggered, or when the values at a specific time step are inspected after the simulation run has been performed. Assuming that some variable(s) have suspicious, or maybe clearly wrong values, one starts analyzing the equations that were used to compute them, going backwards in the causality chain determined in the BLT, and trying to locate the model error that caused the computation of the wrong values.

The solution of the equation(s) also depends on the values taken by all the other known variables showing up in the equations, either states or other unknown variables previously computed in the BLT. The debugger allows to inspect the values taken by these variables, as well as the equation(s) in which they were solved for. Then, the same activities will be possible recursively on this new set of equations: understanding where they come from in the equation transformation chain, as well as inspecting the values of the variable(s) they depend upon.

## 2.3 Debugging Time Integration Problems

The requirements for the debugging of *time integration* problems are quite different. Unrecoverable errors generated by the ODE solver should be reported to the debugger using some kind of unified representation (e.g., using XML), which is as independent as possible from the specific solver used. Of course, some errors will only make sense for a subset of solvers; for example, singular Jacobians are only relevant in the case of implicit solvers; event chattering is only relevant for solver with state event detection.

The first kind of error that can arise in solvers with state event detection based on zero crossing function is chattering: if a large number of events takes place in a very short time interval, then the debugger reports the corresponding zero-crossing functions and allows to back-track them to their original formulation in the source code, as well to inspecting the values of all the variables involved in them in the last accepted time steps.

It may also be the case that chattering arises without any event being generated, if the `noEvent()` operator is incorrectly placed around a discontinuous expression

inside a model equation, or if some functions in the model generate results which are discontinuous w.r.t. their inputs (recall that Modelica functions do not generate events). This situation can be detected by monitoring the step size, and detecting the fact that the step size has been reduced to very small values for a very large number of step sizes.

In order to identify the root cause of the problem, it is necessary that the ODE solver can report which component(s) of the state vectors have the largest estimated errors, and are thus mainly responsible for the excessive step size reduction. The debugger will then point the end user to the equations that are used to compute the corresponding derivatives, using the same mechanism adopted for the initialization and casualization steps. Wildly oscillating values of the derivatives will be observed across the last time steps, and it will then be possible to analyze the expressions leading to these oscillations, eventually locating the root cause of the problem.

Another possible error can arise at the ODE solver level if the underlying differential equations have a finite escape time, i.e., one or more elements of the state vector go to infinity as time approaches a certain finite value. The main symptom in this case is very similar to the previous case, i.e., the step size is greatly reduced and the simulation seems stuck at a certain point in time.

The root cause can also be identified in this case if the solver reports the component(s) of the state record that mostly contribute to the error estimate, so that the debugger can allow the user to inspect the equation(s) that compute the corresponding derivatives. The values of these derivatives will constantly grow from one step to the next one, rather than oscillating wildly as in the previous case. Again, by careful inspection and analysis, it might be possible to understand the root cause of the problem and fix it.

## 2.4 Debugging Homotopy-based Initialization Problems

If the `homotopy()` operator is used for initialization, two extra stages are added to the debugging of the initialization problem. First, the set of initial equations using the simplified expression is presented. The BLT structure of this problem might be substantially different (and hopefully simpler) than that of the actual initialization problem, but the way it is presented in the GUI to the user for analysis is the same as for the actual initialization problem.

The second stage is the homotopy transformation. From a GUI perspective, this is very similar to the simulation phase as there are several steps involved. Each might be accepted, rejected, or eventually fail if the errors cannot be recovered by taking shorter steps. Also, similarly to the simulation phase, errors might be reported that arise while solving the equations in the BLT sequence (as in the initialization and casualization problems), but also some system-level errors might be reported by the homotopy solver itself, e.g., in case of homotopy path bifurcations, similarly to problems reported by the ODE solver during time integration.

The GUI is therefore similar to the one used for debugging errors during simulation, with the following differences:

- The set of unknowns includes states and parameters;
- the set of equations include initial equations and parameter-binding equations
- All occurrences of the homotopy operator [14] in the equations are transformed into  $\lambda * actual\_expr + (1 - \lambda) * simplified\_expr$ ;
- The independent variable which is stepped is not time but rather the  $\lambda$  homotopy parameter.

## 3 Debugger Graphical User Interface

In order to visualize the transformations performed and the operations taken by the solver to solve for a variable and its corresponding equation(s), a *transformations browser* (Figure 1; Figure 2; Figure 3) has been created.

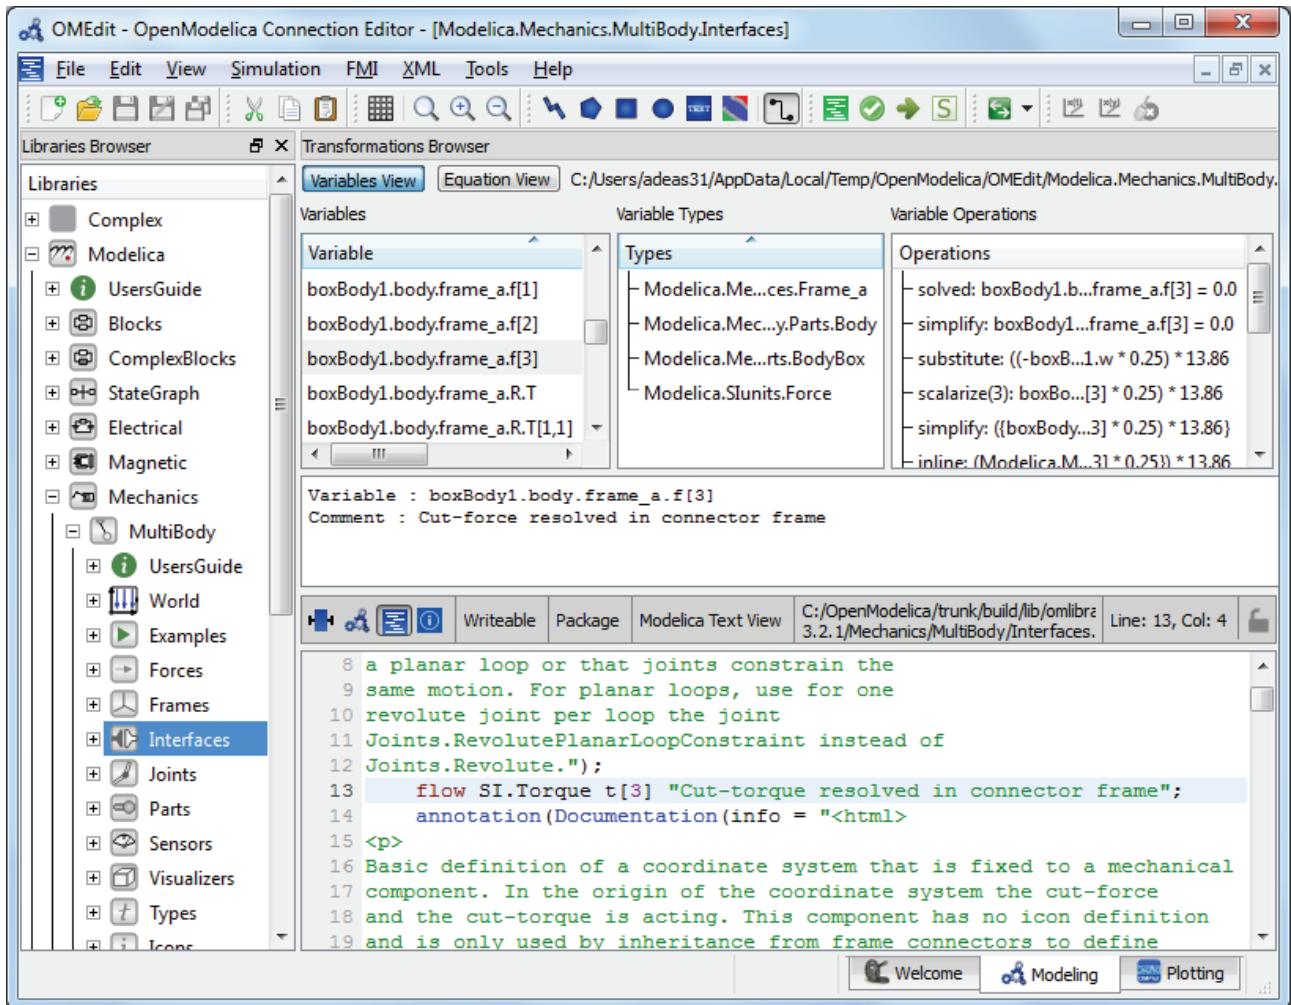

The transformations browser lists the variables along with their respective types hierarchy, operations performed, equations which defines the variable and equations which are using the variable. The types can be used to navigate to the specific class.

Double clicking on the equation updates the transformation browser and shows the list of operations and variables involved in the solution of the equation. See Figure 3.

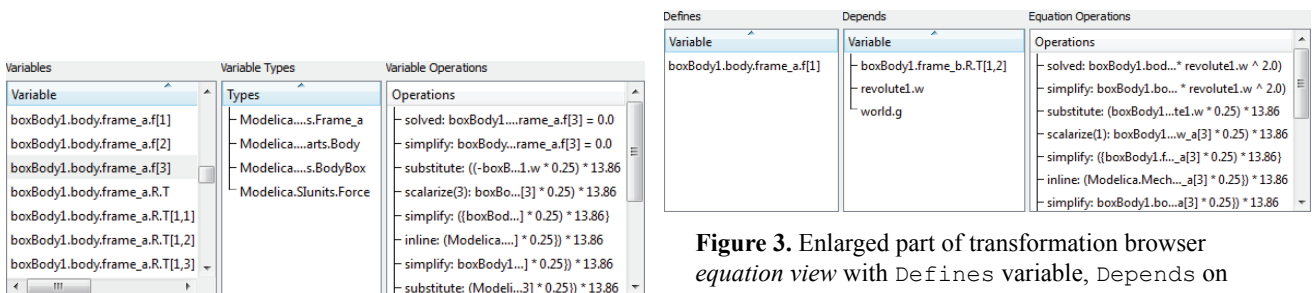

The transformation browser provides two views:

- Variables view
- Equation View

The data needed to build the structures shown in the GUI, i.e., the structural information about the equation systems, and the equation transformation traces, are loaded from an XML file which is generated by the OpenModelica compiler, see Section 4 for more details.

**Figure 1.** Transformations browser variables view with columns: Variables, Variable Types, Variable Operators.

**Figure 2.** Enlarged left part of variable info in transformations browser *variable view* with columns: Variables, Variable Types, Variable Operators.

When a numerical error is reported, clicking on the “Debug more” link at the end of the error report brings up the debugger showing the equation(s) involved in the error.

**Figure 3.** Enlarged part of transformation browser *equation view* with Defines variable, Depends on variable, Equation Operators operations like solved, simplify, substitute, etc.

## 4 Transformation Tracing

The underlying implementation of the transformation tracing mechanism is described in more detail in [7]. Some further improvements are present in this version.

The key idea introduced in [7] is to encode and store in a list all transformations that are performed by the Modelica compiler on the model equations, such as symbolic solution, alias elimination, symbolic differen-

tiation, etc. Because every operation is stored, it is possible to replay the operations and verify that the tool only performed sane operations during translation. This list of operations is then output to an XML-file (Figure 4) which is parsed by the debugger.

```
<simplify>
  <before>
    Nand.TP1.G.i + Nand.TN1.G.i + (-Nand.x2.i)
    = 0.0
  </before>
  <after>
    Nand.TP1.G.i + Nand.TN1.G.i - Nand.x2.i
    = 0.0
  </after>
</simplify>
<substitution>
  <before>
    Nand.TP1.G.i + Nand.TN1.G.i - Nand.x2.i
  </before>
  <!-- list of intermediate results -->
  <exp>0.0 + 0.0 - (-VIN2.i)</exp>
</substitution>
<simplify>
  <before>0.0 + 0.0 - (-VIN2.i) = 0.0</before>
  <after>VIN2.i = 0.0</after>
</simplify>
<solved>
  <lhs>VIN2.i</lhs>
  <rhs>0.0</rhs>
</solved>
```

**Figure 4.** List of equation transformations in the model  
Modelica.Electrical.Analog.Examples.NandGate.

The XML-file contains all the variables and equations used to solve the model, as well as variables that have already been solved for, alias relations, and so on. The equations are split into several groups, such as start-value equations, initial equations, regular equations, since the same variable may have different equations defined for it in different phases of the program.

These groups are related to how the compiler decided to numerically solve simulations. For example, the file includes the equations generated for the Jacobian, which is not used by all numerical ODE/DAE solvers.

Each equation knows the variables it solves for, as well as the variables it uses. This enables fast lookup of parents, children, and siblings in the BLT matrix. When reading the file, information is propagated to variables in a way such that each variable also knows the equation(s) where it is defined. This is again to ensure that the debugger can perform cheap lookup operations.

In the case of strongly connected components, an equation index will point to a set of equations (linear and nonlinear systems of equations in OpenModelica

are defined as a set of equations and variables to solve for). The generated code knows the index of an equation in the XML-file, so in case error or diagnostic messages are generated, a link to the equations and variables associated with this index can be provided to the debugger.

The message routines have been updated to take a list of equation indexes as an option, as well as output the messages as structured XML. This enables the debugger to read the messages and insert links to equations as appropriate.

This approach allows a user to debug simulations even if he/she did not run the simulation through the debugger, because it is possible to perform post-mortem debugging only based on the messages and diagnostics produced by the simulation executable.

There is no additional overhead during regular execution except reading and writing the additional information in the XML-file. This can be done by a thread running in the background and takes only a few seconds even for the large EngineV6 model which both has many equations and many symbolic operations performed on each equation.

For error-messages there is an additional overhead of creating an error message that contains all the relevant information. This is a small one-time cost for error, which are hopefully infrequent. Consequently, the detailed error messages are output even if the user had not decided to debug the simulation before he started it since it will help him figure out why things went wrong.

## 5 Run-Time and Event Related Implementation

The run-time system performs the actual simulation of a Modelica model, in which the solution process is done by different solvers that cooperate in a master-slave hierarchical configuration, with the ultimate master being the end-user:

- ODE solver
- Functions computing the derivatives and algebraic variables
- Function computing the initial states and the values of parameters
- Function computing event points
- Linear equation solvers
- Nonlinear equation solvers

All of them may fail with different kinds of errors depending on the solver, generally because of numerical issues (e.g. singular Jacobian, no convergence, too tight

tolerance). However, at the bottom level they all share particular error types:

- Evaluation of expressions
  - Division by zero.
  - Functions called outside their domain (e.g.:  $\sqrt{-1}$ ,  $\log(-3)$ ,  $\text{asin}(2)$ ).
  - Evaluation of non-integer powers with negative argument
- Assertion violations for the model

In general some errors can be recovered automatically by the system (e.g. by re-trying with a shorter time step), whereas others abort the simulation and are reported to the user, which can then enter the debugging mode.

If an error cannot be recovered by the solver hierarchy, informative diagnostics are provided to the user. The diagnostic error message includes the corresponding equation block, the involved variables and their values. Furthermore the hierarchical context of the error is important to be able to classify it.

In the next step the user may be able to enter the debugging mode, where the simulation can be re-run to an accepted step just before the error occurs again. The last accepted step corresponds to the last point in time in the result file created in the first run. This point in time can be a breakpoint for debugging mode.

In the debug mode breakpoints are interpreted like zero-crossings, but without the time-consuming search process which the numerical solver does — the simulation just breaks if the condition becomes true.

Then the step that caused the failure is executed in a verbose mode, where informative diagnostic is provided for every equation that needs to be solved till the error occurs again. This allows the user to trace the solution process and if necessary, to engage by changing the model.

## 6 Example Models for Debugging

In this section some simple test cases are shown which demonstrate various possible error scenarios, and how a debugger can help their troubleshooting.

### 6.1 Chattering Models

In the model `ChatteringEvents1`, chattering takes place after  $t = 0.5$ , due to the discontinuity in the right hand side of the first equation. Chattering can be detected because lots of tightly spaced events are generated. The debugger allows to identify the equation from which the zero crossing function that generates the events originates.

```
model ChatteringEvents1
  Real x(start=1, fixed=true);
  Real y;
  Real z;
equation
  z = if x > 0 then -1 else 1;
  y = 2*z;
  der(x) = y;
end ChatteringEvents1;
```

Also in the model `ChatteringNoEvents1`, chattering takes place after  $t = 0.5$ , due to the discontinuity in the right hand side of the first equation. However, events are not generated in this case, because of the `noEvent` operator. If a variable-step-size integration algorithm with error control is used, the time step will be reduced to very small values once the discontinuity is hit, and this can be detected by monitoring the value of time at each time step.

The variable step size solver should be able to report which state variable(s) give the biggest contribution to the error estimate, thus causing the step size reduction. The corresponding derivative shows very high frequency oscillations between two values. The end user can then use the BLT navigation functionality of the debugger to investigate which variable/equation is introducing the discontinuity.

```
model ChatteringNoEvents1
  Real x(start=1, fixed=true);
  Real y;
  Real z;
equation
  z = noEvent(if x > 0 then -1 else 1);
  y = 2*z;
  der(x) = y;
end ChatteringNoEvents1;
```

Regarding `ChatteringFunction1`, after  $t = 0.5$ , chattering takes place due to the discontinuity in the right hand side of the first equation. The discontinuity is caused by a discontinuous function, which does not generate events.

The considerations regarding variable-step solvers, derivatives, and debugger BLT navigation are the same as for the previous example `ChatteringNoEvents1`.

```
model ChatteringFunction1
  Real x(start=1, fixed=true);
  Real y;
  Real z;

function f_sign
  input Real x;
  output Real y;
algorithm
  if x > 0 then
    y := 1;
  elseif x < 0 then
    y := -1;
  else
    y := 0;
  end if;
```

```

end f_sign;

equation
  z = Functions.f_sign(x);
  y = 2*z;
  der(x) = y;
end ChatteringFunction1;

```

## 6.2 Models with Different Numerical Failure Modes

The `NonlinearSolverFailureInitial` model describes a simple hydraulic system with a pump, followed by a valve, which fills a reservoir.

The initial value of the level of the reservoir is too high for the pump sizing, so the pressure `p2` is too high and consequently the nonlinear algebraic system of equations that determines `p1` and `w_pump` has no solution.

It is possible to find a solution to the system either by lowering the initial value of `y`, and thus the pressure `p2`, or by increasing the value of the parameter `dp0`, increasing the head the pump can provide.

The debugger can show the dependency of the nonlinear system of equations on the parameters `dp0`, `a1`, `a2`, `a3`, and `Kv` (also showing their values), as well as the dependency on `p2` (which has a too high value). Once one understands that `p2` is too high, it should be possible to continue the analysis, looking at the equation that determines `p2`, which in turn depends on the value of the state `y`, which is the root cause of the problem.

The nonlinear system that cannot be solved has five unknowns: `w_pump`, `dp_pump`, `dp_valve`, `sqrt_dp`, and `p1`, which can be easily reduced to one by using `dp_pump` as a tearing variable. The debugger can show the torn variables and the tearing variables, as well as the corresponding torn equations and implicit residual equations, and allows to track the values of all five variables during the iterations of the Newton algorithm.

```

  SI.Temperature T1
    "Pump discharge temperature";
  SI.Time tau=1
    "Time constant of temperature sensor";
equation
  dp_pump = p1 - patm "Pump dp";
  dp_valve = p1 - p2 "Valve dp";
  dp_pump = dp0 - a1*w_pump^2;
  w_pump = Kv*sqrt_dp;
  sqrt_dp = dp_valve/
    (dp_valve^2 + dp_small^2)^0.25;
  W = a2 + a3*w_pump;
  w_pump*(h1 - h0) = W;
  rho*A*der(y) = w_pump + w_extra;
  p2 = rho*g*y + patm;
  h0 = cp*(T0 - Tref);
  h1 = cp*(T1 - Tref);
end NonlinearSolverFailureInitial;

```

A simple modification of the previous model allows demonstration of the failure of the nonlinear solver in the causalization stage during simulation. The initial value of the level is reduced to 20, so that an initial solution can be found.

```

model NonlinearSolverSimulation
  extends NonlinearSolverFailureInitial(
    y(start=20), w_extra=0.2);
end NonlinearSolverSimulation;

```

In this case the reservoir is filled both by the pump and by an extra source. The mass flow rate of the pump `w_pump` is determined by a nonlinear system with five unknowns: `w_pump`, `dp_pump`, `dp_valve`, `sqrt_dp`, and `p1`, which basically computes the operating point of the pump as the intersection between the pump head curve and the load (valve + reservoir head) curve. Note that these curves have two intersections (also see `NonlinearSolverFailure3` later on). As the level increases, `w_pump` is reduced, and the two intersections get closer to each other, until at time  $t = 269$  they collide, making the system singular. As the level increases further due to the extra source, this system ceases to have any solution. This is a typical bifurcation pattern in nonlinear systems.

The debugger can show that the condition number of the Jacobian of the nonlinear system gets bigger and bigger as the critical time when the two operating

curves become tangent to each other, suggesting that this system becomes singular for some reason. Understanding the reason why this happens requires physical insight into the model.

The model can be fixed by adding some mass storage depending on the pressure  $p_1$ , in order to avoid the singularity in determining  $p_1$ , and also by using a more realistic cubic curve for the pump model, so that when the limit level is reached, the solution will jump to a big negative pump flow. Again, this requires physical insight into the validity range of the implemented model.

Another slight variation of the model allows demonstrating the case of finite escape time.

```

model FiniteEscapeTime
  extends NonlinearSolverFailureInitial(
    y(start=20));
  SI.Temperature Ts(start=T0);
  equation
    tau*der(Ts) = T1 - Ts;
  initial equation
    der(Ts) = 0;
end FiniteEscapeTime;

```

As the reservoir level increase, the flow rate  $w_{\text{pump}}$  goes to zero. When it does, the energy balance equation causes the specific enthalpy  $h_1$ , and thus the temperature  $T_1$ , to go to infinity.

The temperature  $T_1$  is the input of a first-order linear system, representing the temperature sensor dynamics. If a variable step-size solver with error control is used, it will try to compute the state trajectory, which also goes to infinity, so the solver eventually gets stuck at time  $t = 664$ .

If the ODE solver reports information on the state whose error estimate is causing the step size to be reduced, ( $T_s$ , in this case), then the debugger can point the end user to its derivative  $\text{der}(T_s)$ . It will be shown that it depends on  $T_1$ , whose values can be seen to grow indefinitely over time.  $T_1$  is shown to depend on  $h_1$ , which also goes to infinity. Finally,  $h_1$  depends on the energy balance equation, which depends on  $w_{\text{pump}}$ . At that point it will become apparent that as the flow rate  $w_{\text{pump}}$  goes to zero, the model becomes ill-posed. The solution in this case is to change the pump model, by adding to the energy balance some dynamic energy storage and/or some heat transfer to the ambient, in order to avoid the zero-flow singularity.

Finally, another small change to the original model presented in this section allows to demonstrate the debugging of models where the wrong initial solution is picked by the nonlinear solver.

```

model WrongInitialSolutionSelected
  extends NonlinearSolverFailureInitial(
    y(start=20),
    dp_pump(start=-1000));
end WrongInitialSolutionSelected;

```

The operating point of the pump is determined by a nonlinear system with five unknowns:  $w_{\text{pump}}$ ,  $dp_{\text{pump}}$ ,  $dp_{\text{valve}}$ ,  $\text{sqrt}_{dp}$ , and  $p_1$ . It is assumed here that  $dp_{\text{pump}}$  is selected as a tearing variable. At time  $t=0$ , this system has two solutions, one with positive  $w_{\text{pump}}$ , and the other one with negative  $w_{\text{pump}}$ . If the start value of the tearing variable  $dp_{\text{pump}}$  is chosen incorrectly, the solver will converge to the negative solution, then lock onto it for the rest of the simulation.

When the user sees the negative  $w_{\text{pump}}$  in the simulation (which is physically wrong), he/she should be able to analyze how this value was found at time  $t = 0$ . The debugger shows that  $w_{\text{pump}}$  is solved by that nonlinear system, and shows the values of the tearing variables and of the torn variables at each iteration step.

It will then become apparent that the start value of the tearing variable  $dp_{\text{pump}}$  leads to a negative value of the torn variable  $w_{\text{pump}}$ , leading to the solution of the problem, i.e., changing the start value of  $dp_{\text{pump}}$  to a value that allows convergence on the desired solution.

## 7 Background and Related Work

Modelica is a declarative language that makes writing equations easy while still producing efficient code. However, traditional debugging tools like GDB [12], Valgrind [19], or any of the other tools described in [18] assumes that the program being debugged is statement based. It also assumes that the user knows something about what the program is doing. This is fine if you are a Modelica compiler developer working on fixing some segmentation fault in your own code. A GDB-based approach exists for Modelica [4]; it works fine for debugging algorithms in functions.

But as a Modelica user you know very little about the internals of the run-time system. For example, there is speculative execution while simulating a model making debugging with GDB confusing.

There exists previous work on debugging in Modelica. Bonus [9] proposes a semi-automated dynamic (run-time) debugging of models where the user has to provide a correct diagnostic specification of the model which is used to generate assertions at runtime. Moreover, starting from an erroneous variable value the user explores the dependent equations (a slice of the program) and acts like an “oracle” to guide the debugger in finding the error.

Sjölund [7] is used as the main basis of the equation debugging part of this work. It was mainly focused on tracing operations in the compiler backend. It has been

extended with structured error messages from the simulation run-time system as well as an actual debugger.

Pop et al [3], [4] describe an integrated debugging approach based on a dependency graph. Edges in that dependency graph can be computed by the transformational tracing mechanism mentioned in Section 4.

## 8 Current Status

At the time of this writing, the implementation of the debugger framework in the OpenModelica environment is mostly complete but still missing some parts.

This debugger framework has three main parts: the tracing of symbolic operations in the backend of OpenModelica, reporting run-time errors in simulations, and the debugger implemented as an extension of the OMEdit graphical user interface.

The tracing of operations is complete, and the mapping of error positions in the low level generated code to the high-level model from where they originated. However, the reporting of run-time errors only works for a subset of problems at the moment.

The generation of the XML file with the transformation tracing, and its subsequent representation in the OMEdit GUI are fully implemented. Some types of numerical errors (e.g., chattering) can already be debugged as described in the paper.

However, the interface to the numerical solvers (both for the casualization and for the time integration steps) is still incomplete. Also the functionality of analyzing the results of simulation runs (which did not generate errors) at specific points in time is not implemented yet.

It is planned to have the implementation with the abovementioned additional functionality completed by fall 2014.

## 9 Conclusions and Future Work

We have presented a set of problems of simulating Modelica models that benefits from increased debugging tool support. We have also presented a design and implementation of the first (to our knowledge) documented debugging framework that can handle this set of problems.

The debugger is operational and has been tested on rather large models without noticeable run-time overhead. It is able to map error positions from low-level compiled simulation code to the corresponding source level equations in the Modelica model.

We believe that this kind of debugging support will significantly improve the ease-of-use regarding application modeling with Modelica compared to the current

situation typically needing a large amount of trial-and-error and a lot of expertise in the internal mechanisms of Modelica model compilers and simulation run-time systems. This can speed up the acceptance and use of Modelica in the engineering community.

Future work includes creating additional specialized debugging views including a view to display non-convergence of non-linear equation systems.

## 10 Acknowledgements

This work has been supported by the Swedish Strategic Research Foundation in the EDOp projects and Vinnova in the RTSIM and ITEA2 MODRIO projects, and by VR. The Open Source Modelica Consortium supports the OpenModelica work.

## Abstract

Engineers need to perform many different types of analyses as they design systems. Modelica has become a leading language to support numerical simulation. As a consequence there is widespread understanding of Modelica and a large number of Modelica model libraries available. This paper addresses the task of using formal methods to derive system properties such as whether a design meets its requirements for all possible inputs. We report on our experience building a qualitative reasoner operating on Modelica models. In this paper, we highlight five Modelica modeling practices that impede the application of formal methods.

## 1 Introduction

Modelica [Fritzson, 2004] is a powerful language for specifying the behaviors of components represented by declarative constructs connected through power ports. Modelica provides designers with large libraries of standard models and compile time computation to create large models. These features attract designers interested in numeric simulation and researchers developing new analyses. In contrast, the languages qualitative reasoning [Weld and de Kleer, 1989] and other hybrid system verification methods (e.g., HybridSAL [Tiware, 2012]) require equation-based models. Engineers use these formal methods to prove that systems will never reach critical states for all possible parameter values in a section of the design space. In previous work, we have discussed how qualitative reasoning can be used on Modelica models consisting only of a subset of the language [Klenk *et al.*, 2012].

In addition to this common core, Modelica allows designers to specify behavior using algorithms and provide advice for simulation engines. While designers desire this flexibility and control, these features make qualitative reasoning and other formal methods difficult to apply to Modelica models. In addition to simulation advice and explicit algorithms, we identify three other modeling practices that hinder the application of formal methods: unnecessary component model complexity, use of computational state, and incomplete models.

This paper is structured as follows. We begin with a brief overview of qualitative reasoning. Then, we discuss how the Modelica compiler may be used by formal methods. After which, we provide examples of each class of

hindrances along with suggestions for improving the applicability of Modelica models for formal methods. We close with a discussion of related work and some general reflections on modeling.

## 2 Qualitative reasoning and Design

Qualitative reasoning has its roots in automating reasoning about physical systems [Forbus, 1984][Kuipers, 1994][de Kleer and Williams, 1991]. Based on the intuition that engineers employ qualitative reasoning extensively throughout the design process, numerous researchers have sought to apply qualitative reasoning to design problems including functional reasoning [Everett, 1999][Wetzel and Forbus, 2009], diagnosis [Struss and Price, 2004], and automated FMEA generation [Snooke and Price, 2012]. An important subtask is *qualitative simulation* [Forbus, 1984][Kuipers, 1994], which provides an abstract description of the possible behaviors of a mathematical model. We illustrate qualitative simulation as well as some uses in the design context with a series of examples.

First, consider the spring block system in Figure 1 with the initial condition of a displacement of 5 meters compressing the spring. Given a set of numeric parameters and a simulation duration, Modelica produces a numeric simulation (i.e., a sequence of real values for each variable). On the other hand, qualitative simulation begins by creating a set of abstractions for each variable. The simplest set is three qualitative values ( $Q_-$ ,  $Q_0$ , and  $Q_+$ ) corresponding to the sign of the real valued quantity. Each continuous variable can have as many higher-order derivatives as necessary, each of which specifies a direction of change ( $\downarrow$ (DEC),  $\rightarrow$ (STD),  $\uparrow$ (INC)) at that derivative order. Qualitative simulation determines all possible sequences of qualitative states a system can go through over time, called an *envisionment*. Changes in the qualitative state occur when a variable or its derivative reaches a *landmark* (e.g., the displacement of the block crosses zero, the velocity of the block crosses zero). Crossing a landmark occurs in an instant that has no duration (represented as a rectangle) and approaching or departing a landmark occurs over an interval of time (represented as an oval). The numeric simulation produces a sequence of numbers that must be interpreted by the designer to understand the behavior. On the other hand, the envisionment illustrates directly that this system is oscillatory because the graph is a loop (i.e., the system returns to the same qualitative state). Furthermore, while the numeric simulation results apply to specific values for the mass and compliance of

(a) Spring block system

(b) Envisionment with qualitative values for the velocity and its derivative are shown. Each state is assigned a unique id. Ovals represent qualitative states that exist over an interval of time and rectangles represent qualitative states that exist only for an instant.

Figure 1: Qualitative simulation example

the spring, the envisionment illustrates that the behavior of the system in Figure 1 will be oscillatory for every set of parameters.

One reason for performing simulations is to determine if a system will meet some specified requirement. Figure 2 illustrates a simple rotational mechanical system with a specified requirement that the angular velocity must exceed 1 rad/s. This requirement can be encoded in Modelica using an enumerated type: Unknown, Success, Violated. The value of this variable begins as Unknown and changes to Success if the angular velocity of the flywheel exceeds 1 rad/s. As shown in the Modelica simulation (Figure 2), the system does not meet the requirement. Meanwhile, the envisionment (Figure 2) contains an interval in which the flywheel is accelerating followed by two branches: one where the requirement is met (shown as a green uparrow) and one where the inertia reaches

its asymptote (shown as a blue rectangle). This multi-trajectory simulation illustrates the range of behaviors that are possible given underspecified parameters (e.g., the moment of inertia, applied torque, and damping coefficient are known only to be positive). The Modelica simulation in Figure 2 corresponds to the the following trajectory of qualitative states:  $48 \rightarrow 122 \rightarrow 313$ . Because this environment includes a trajectory in which the requirement's value is Success, the designer knows that this topology may satisfy the requirement with different parameter values (e.g., increasing the torque or decreasing the damping factor).

Figure 2: Qualitative Simulation and Requirements

(a) Modelica configuration with requirement that the flywheel reaches 1rad/s.

(b) Modelica simulation demonstrating that the current set of parameters does not meet the requirements within 5 seconds.

(c) The envisionment shows that this configuration could meet requirements with a different set of parameters. Cyan nodes represent terminal states, magenta nodes represent discrete events, and green uparrow nodes represent states that meet requirements.

Our intuition is that designers use this qualitative under-

standing of the design space to make decisions about components, parameters and configurations. Qualitative simulation is applicable early in the design process because it operates without completely specified parameters. Furthermore, qualitative simulation can be used to automate a number of the reasoning tasks designers perform during early design, answering such questions as:

- Could this configuration of components perform the desired function?
- What kinds of failures might this design have?
- How would this system behave when increasing a particular parameter?

Unfortunately, current qualitative simulation approaches are unable to make use of many existing Modelica models. In the rest of this paper, we discuss features of the Modelica language and practice that hinders the reuse of Modelica models by formal methods such as qualitative reasoning.

### 3 Modelica models for formal methods

Modelica's reuse and flexibility are central to its appeal among designers, engineers, and researchers. Unfortunately, these features create difficulties for applying formal methods. Some problematic features are: compiler interaction, artifacts for numeric simulation, unnecessary component model complexity, algorithms, sequential states, and incomplete models. For each issue, we will attempt to answer three questions:

- Why do designers use it?
- Why is this difficult for formal methods?
- What should be done to enable formal verification?

Before we discuss Modelica language issues, we discuss how Modelica compilers assist in our efforts to perform qualitative reasoning with Modelica models.

#### 3.1 Using the compiler to facilitate other analyses

Modelica tools include a compiler that takes as input a Modelica model and through a sequence of processes produces executable code to perform numeric simulation. Access to intermediate results during the compilation process facilitates other analyses. Here we highlight three aspects of the compilation process we have found useful.

##### Model construction language

Modelica has a powerful model construction language including iteration and conditional declarations. For example, the Damper model (shown in Figure 3) includes a conditional heat port, which allows the same damper model to be used in systems that consider thermal connections and those that do not. Also, compilers perform a number of optimizations on the model including index reduction and removal of redundant variables. These optimizations are applicable to qualitative reasoning as well. Therefore, our approach uses an XML representation of the hybrid-DAE produced by OpenModelica [Parrotto *et al.*, 2010]. Furthermore, we encourage the ongoing efforts to standardize an XML representation of the compiled model across Modelica tools.

##### System initialization

System initialization is a well-known difficult problem, and Modelica provides a number of language constructs to direct the solver to the initial state [Mattsson *et al.*, 2002]. These include the use of the `:start` and `:fixed` keywords, initial equations and initial algorithms. Qualitative simulation also requires knowing the initial values of the system variables. Therefore, we use OpenModelica to solve the initial equation system for a consistent set of initial values from which to begin our analysis.

##### Function inlining

Many Modelica functions are merely mathematical relationships between input and output variables. Consider the `from_kmh` function in the Modelica Standard Library shown in Figure 4. Function inlining is performed by many Modelica compilers to replace calls to these functions by their equivalent equations. The problems with analyzing arbitrary functions will be discussed in Section 3.4. Therefore, having the compiler perform these optimizations assists in translating Modelica models for use in formal methods.

Figure 4: Function that converts km/h to m/s

```
function from_kmh;
  input NonSIunits.Velocity_kmh kmh ;
  output Velocity_ms "metre per second value";
algorithm
  ms := kmh/3.6;
end from_kmh;
```

#### 3.2 Artifacts of numeric simulation

Modelica is primarily a language for modeling and simulating mathematical models that evolve as a function of time. Consequently, there exist many constructs to assist with issues that arise in numeric simulation. While some are irrelevant for formal methods (e.g., `noEvent` and `smooth`), in this section, we discuss three that complicate formal methods analyses.

##### Equality involving continuous time variables

Modelica events occur at zero crossings. Therefore, it is not possible to have a condition testing equality of real valued variables,  $s1$  and  $s2$ . Instead, the `Modelica.math.IsEqual` function from the Modelica Standard Library which is computing using Equation 1.

$$result := abs(s1 - s2) \leq eps; \quad (1)$$

While Equation 1 can be translated directly for formal methods, it both needlessly adds complexity to formal analysis and may yield unexpected results. Intuitively, `IsEqual` is testing whether  $s1$  and  $s2$  are equal. If the Equation 1 is directly encoded, the formal analysis will have to consider 7 cases: (1)  $s1 - s2$  is negative and more than  $eps$  from 0, (2)  $s1 - s2 = -eps$ , (3)  $s1 - s2$  lies between  $-eps$  and 0, (4)  $s1 - s2 = 0$ , (5)  $s1 - s2$  is positive and less than  $eps$ , (6)  $s1 - s2 = eps$ , (7)  $s1 - s2 > eps$ . In effect, it treats  $eps$  as an important parameter the system. As a consequence the number of states needed to be analyzed grows exponentially in the number of `IsEqual`'s translated in this way. Finally, the formal analysis could

Figure 3: Damper model from the Modelica Standard Library includes a conditional heat port connection that is set during model instantiation

```

model Damper "Linear 1D translational damper"
  extends Translational.Interfaces.PartialCompliantWithRelativeStates;
  parameter SI.TranslationalDampingConstant d(final min = 0, start = 0) "Damping constant";
  extends Modelica.Thermal.HeatTransfer.Interfaces.PartialElementaryConditionalHeatPortWithoutT;
equation
  f = d * v_rel;
  lossPower = f * v_rel;
end Damper;

```

produce incorrect results because it will accept as possible states in which  $s1$  is not equal to  $s2$  which is clearly against modeler's intent. Because formal methods allow for equality between continuous-time variables, the best solution is to simply translate `IsEqual(s1,s2)` to `s1 == s2`.

### Smoothing functions

Another piece of advice supplied by the model to the simulation engine concerns smoothing functions. For example, the function `Modelica.Fluid.Utilities.regStep` approximates a step function with a second order polynomial that is continuous and differentiable. Unless the transient behavior is the focus of the model, formal methods are more applicable to the idealized behaviors.

### 3.3 Unnecessary component model complexity

Modelers should be as concise and clear as possible when authoring models.

#### Optional model parameters

The inheritance features in Modelica make it easy to provide different variants of components that account for different behaviors. Therefore, in each model, every parameter should affect the behavior of the model. When this is not the case, the modeler has increased the complexity of the model unnecessarily. Consider the `w_small` parameter `PartialFriction` model. The default value of this parameter is `1e10` and the comment directs the engineer to set this to a small value if particular discontinuities are expected. This absurdly high value is to prevent it from affecting the simulation. Making these two separate models that inherit from the same model would facilitate formal methods by considering the `w_small` parameter only when it is necessary. Otherwise formal analysis will have to needlessly analyze the distinction between `w_small` and `w`.

#### Component modes

The evolutionary development of the Modelica language is apparent in the models of the Modelica Standard Library. For instance, many models use `Integer` variables to define a mode of operation for the model. However, these variables are typically unbounded, and often the default variable value of zero is not an applicable mode. Using enumerations would provide a definite set of modes of operation for these variables. However, even this is not sufficient. In some tool systems, such as `OpenModelica`, parameter variables of enumerated types are not required to be initialized to any particular value, and in that case

they default to the integer default value of zero, which is an invalid integer value for that enumerated type! In general, the semantics of operating modes, and more specifically enumerations (and parameters), seems to need more work in Modelica.

### 3.4 Imperative Code

Modelica algorithms can be executed at two times: flattening and simulation. All of the former algorithms pose no difficulty to formal analysis as they are executed before the DAE is created. Imperative code embedded in the DAE, typically in functions, to be executed at run time presents a fundamental challenge. Imperative code is important to model designers because certain numerical computations are easier to express as algorithms as opposed to equations. The Modelica language is Turing-complete, so proving properties of arbitrary Modelica programs is as hard as proving properties of any program. And proving properties of programs is a challenging intellectual field all to its own. Formal methods cannot be expected to analyze such algorithms. For common functions, we have created qualitative equivalents. For example, interpolation tables are essential to modeling complex physical systems, and, therefore, we have created an analogous concept for qualitative reasoning. There is independent interest in the Modelica community in elimination of imperatives when possible. For example, function inlining converts some imperatives to constraints automatically [Papadopoulos *et al.*, 2012].

We have applied our analysis technique to a wide variety of models. Too often we encounter needless imperatives. For example, consider:

```

Model Single_Clutch_Controller
  Output Real y;
  Input Integer u;
  parameter Integer num_gears = 5
  parameter
    Integer gear_nums[num_gears] = {-1,1,2,3,4}
  parameter Real engagement[num_gears]
    = {0.0, 1.0, 1.0, 0.0, 0.0};
algorithm
  y := 0.0;
  for i in 1:num_gears loop
    if u == gear_nums[i] then
      y := engagement[i];
    end if;
  end for;
end Single_Clutch_Controller;

model GBX_5_clutch_controller
  ...

```

```

Modelica.Blocks.Interfaces.RealOutput clutch_1;
Single_Clutch_Controller controller_c1
  (num_gears=num_gears,
   gear_nums=gear_nums,
   engagement=c1_eng);
...
equations
  connect(controller_c1.u, gear_selected);
  connect(controller_c1.y, clutch_1);
  ...
end GBX_5_clutch_controller;

```

Given a desired gear, the controller selects the clutch to activate. The algorithm block simply looks up the array index of the desired gear and reads off the clutch needed to engage. The clutch can be modeled as a table:

x	y
-1	0.0
1	1.0
2	1.0
3	0.0
4	0.0
X	0.0

Modelica has a table primitive (which begs the question why it wasn't used in this model). However, this particular table can be expressed as a Modelica equation:

```
y = if (x=1 or x=2) then 1.0 else 0.0;
```

To summarize, our approach to imperative code is:

- For widely used MSL functions such as interpolation we design them as primitives for the qualitative analysis. These function names appear in the XML DAE and thus can be treated as primitives.
- In limited cases, imperative code can automatically be translated to declarative code by function inlining.
- Key MSL models containing imperative code are being rewritten to be purely declarative (or use only known imperative primitives).
- User created functions and algorithms are currently not allowed. One unexplored possibility is the user must annotate the model specifying a piecewise linear approximation of the imperative code's behavior.

### 3.5 Sequential States

Many models include sources that iterate through a sequence of states (`Modelica.Blocks.Sources.SawTooth`) or components that exhibit delayed effects (`Modelica.Blocks.Logical.TriggeredTrapezoid`). The primary way this is handled in Modelica is by triggered Modelica events and setting a discrete-time real value representing the time at which the next state should change. Consider the variable  $T$  in the `TriggeredTrapezoid` model shown in Figure 5.

These models are difficult to analyze due to the non-local effects of the setting of the discrete-time variable. We propose to rewrite them without explicitly referencing time. This is done by using the events to set the rate and then the delayed effects occur when one of the continuous variables reaches a limit.

### 3.6 Incomplete models

Another complicating issue is that model authors frequently build models until their needs are met. While these models produce the simulation results the modeler expects, other analyses may have trouble using them due to untyped variables and operating regions.

#### Untyped variables

Modelica allows modelers to give types to variables, but modelers frequently use `Real` instead of more specific types. The Brake model in MSL defines `mue0` as type `Real` instead of `CoefficientOfFriction`. Automated fault modeling techniques (e.g., FAME [de Kleer *et al.*, 2013]) construct better fault models if variables are typed correctly.

### 4 Related work

The differences between the modeling languages used by engineers (e.g., Modelica, C++) and those used by model checking tools (e.g., finite state automata) hinder the deployment of formal methods in the design process. Researchers have taken both top-down and bottom-up approaches to overcoming this hurdle. Carloni *et al.* exemplify the top-down approach by arguing for a *semantic-aware interchange format* to make formal methods applicable across languages [Carloni *et al.*, 2006]. As an alternative to attempting to unify all hybrid systems languages, bottom-up approaches define automatic translations between subsets of pairs of languages. For example, Lundvall *et al.* translate a portion of Modelica models into hybrid automata for verification [Lundvall *et al.*, 2004]. Our approach follows the bottom-up tradition, and the contribution of this paper is a discussion of five Modelica modeling practices that hinder the automated analyses of Modelica models by formal methods.

### 5 Reflections on modeling

Modelica makes some fundamental semantic choices which are at odds with the formal methods, qualitative reasoning and cyber-physical systems communities. For example, Modelica allows one event to cause another — that is, two instants immediately following one another. Also, formal methods typically model behavior by modes, guards, and constraints. Modelica's guards and modes exist at the system level as conditions, but are not directly accessible from the models. So the common-sense engineering notion of mode has to be expressed by extra boolean variables and conditions. This can lead to very counterintuitive (to an engineer) models (e.g., the transistor models in MSL). For the purposes of our research, we have to accept Modelica's semantics. We do not know yet what problems this will cause.

Our experiences using Modelica models for other analysis purposes motivates some reflections on good modeling practices. In the course of this research, we have had to study and analyze a great many Modelica models. Some models in the MSL are diamonds, other models are disasters. We often wish that the Modelica community employed more standardized modeling practice. Modelica is such a general language that a modeler can write incredibly stupid models. Maybe that is because it is very hard to write clean, concise models. To summarize we suggest the following modeling principles:

Figure 5: Portion of the TriggeredTrapezoid model highlighting the use of discrete-time variables to initialize the timing of state transitions.

```

block TriggeredTrapezoid "Triggered trapezoid generator"
  extends Modelica.Blocks.Icons.PartialBooleanBlock;
  ...

  discrete Modelica.SIunits.Time T
    "Predicted time of output reaching endValue";
equation
  y = if time < T then
    endValue - (T - time) * rate else
    endValue;
  when {initial(),u,not u} then
    ...
    T = if u and not rising > 0 or not u
      and not falling > 0
      or not abs(amplitude) > 0
      or initial() then
        time else
        time + (endValue - pre(y)) / rate;
  end when;
end TriggeredTrapezoid;

```

Figure 6: Portion of the TriggeredTrapezoidPARC model that explicitly states the conditions for state transitions.

```

block TriggeredTrapezoidPARC
  ...
protected
  Real rate;
equation
  when {initial(),u,not u,y>offset+amplitude,y<offset} then
    rate = ...
  end when;
  der(y) = rate;
end TriggeredTrapezoid;

```

1. Models should be easy to understand for both machines and people.
2. Models should be as declarative as possible, even when it's simpler to write imperative code. Such models are easier to understand by both people and machines.
3. Any "advice" to the compiler, especially dealing with small epsilon quantities in models should be done in standardized ways, such as `IsEquals`.
4. All variables should be declared by their physical type.
5. Models should have `assert` statements describing their range of applicability.

# Implementing stabilized co-simulation of strongly coupled systems using the Functional Mock-up Interface 2.0

Antoine Viel  
LMS Imagine  
7 Place des Minimes, 42300 Roanne, France  
antoine.viel@lmsintl.com

## Abstract

This paper addresses the main issue encountered with the co-simulation of coupled systems that exchange energy, i.e. the trade-off between computational performances and numerical stability. This property is first explained in details with the help of a simple generic test system for which a large oversampling with respect to the Nyquist frequency is required in order to keep a good level of accuracy. The linearly implicit stabilization method from [4] is then implemented and tested thanks to the directional directives computation capability of the FMI for Co-simulation 2.0 standard. Some minor extensions to the standard are proposed to efficiently implement the method. When applied to the test system, it is shown that large co-simulation steps can be taken, and hence significant computation time speed-ups are observed.

**Keywords:** *Functional Mock-up Interface; co-simulation; linear system theory; stability*

## 1 Introduction

Among the existing methods for coupling simulation models and software, co-simulation is used for performing transient simulations of coupled simulators<sup>1</sup>. The fundamental principle of co-simulation is to locally decouple in time simulators that are synchronized only through a limited set of coupling variables at scheduled time instants.

The most widespread numerical co-simulation scheme, is an explicit non-iterative Jacobi-type sequence of forward solving steps [7] done by each involved numerical solver (the stepping is described on

figure 1 in the case of two simulators).

Figure 1: The explicit modular stepping scheme applied to the co-simulation of two coupled subsystems.  $H_k$  is the size of the current co-simulation or macro step.

As a consequence of this stepping scheme, each simulator is seen as a discrete dynamical system from the outside, and although each simulator is able to reach convergence if taken alone, the co-simulation process of energetically coupled systems is conditionally stable, even if the system is devoid of algebraic loops. This means that the convergence of the co-simulation process depends on the size of the co-simulation step, also called macro-step. An absolute stability limit does exist beyond which divergence is rapidly reached, and slightly below this limit undamped numerical oscillations still propagate between the subsystems. Divergence and poor accuracy are usually avoided by taking small enough macro-steps, which prevents the numerical solvers from taking large numerical micro-steps and thus leads to reduced computational efficiency with respect to continuously coupled systems that are integrated with a unique variable-step solver.

This property leads to a trade-off between computational efficiency and numerical stability which can be studied on the simple test case of a strongly coupled system introduced in the next section. In a latter sec-

<sup>1</sup>A simulator being defined as the combination of a simulation model and mathematical libraries with a numerical solver, the latter being itself a combination of numerical integrators of ODE or DAE systems, error estimators, step size and order control heuristics, and discrete event schedulers.

tion, a numerical method is then implemented within the FMI for Co-simulation 2.0 framework, and tested with the same system, showing that this trade-off can be significantly enhanced.

## 2 A conditionally stable co-simulated system

### 2.1 Description of the test system

We consider a two degrees of freedom hydraulic system [1] obtained by connecting serially two elementary subsystems (see figure 2) made of:

1. a pipe modeled as a lumped-parameter nonlinear R-I element, with first-mode inertial effects and regular head losses
2. a volume modeled as a lumped-parameter nonlinear C-R element, with fluid-related compressibility effects, and singular head losses due to a leakage to the main circuit tank

The nonlinearities arise from the isothermal fluid properties that relate the density and compressibility to the system pressure, and from the laminar-turbulent friction models of the head losses. Some boundary conditions are introduced to model the surrounding environment: a constant pressure source on the left, and a transient flow rate source on the right.

### 2.2 Analysis of the continuously coupled system

The figure 3 shows the transient response of the continuously coupled system to the change of flow rate applied by the source on the right. The system parameters (pipe length and diameter, roughness, volume, head loss, ...) are chosen to be the same in the left and right subsystems. This choice is made to exemplify the nature of the coupling and its consequences on the dynamics of the coupled system.

Indeed, the dynamics of each subsystem can be studied by linearizing the system around some operating points, for example at the steady state following the first transient, for  $0.5 \leq t < 1$ . Instead of building the nonlinear state space and then evaluating the Jacobian matrix, a better understanding of the dynamics is obtained by analyzing the bond graph of the system.

Following the bond graph analysis of figure 4 and considering that the energy storage and dissipation elements are modeled using linear behaviour law, each elementary subsystem can be modeled by a first order

Figure 3: Transient pressure in the two hydraulic chambers (top) and source flow rate (bottom). Numerical simulation performed with the LSODA variable-step solver

Figure 4: Bond graph of the system showing the partitioning in two subsystems. The coupling variables are  $e_1$  (output effort from first subsystem on the left) and  $f_2$  (output flow from second subsystem on the right).

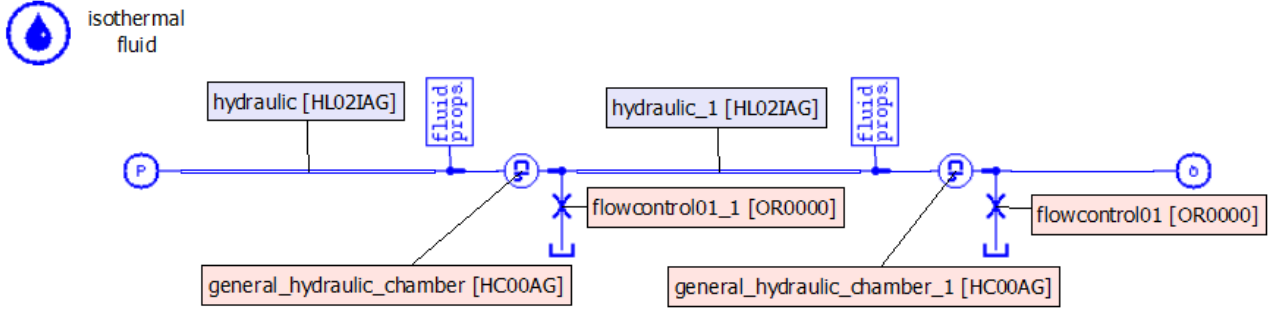

Figure 2: Sketch of an hydraulic two degrees of freedom system obtained by connecting two identical R-I-R-C subsystems built with LMS Imagine.Lab AMESim

linear system of ordinary differential equations in the state variables  $q_i$  and  $p_i$  associated with the C and I energy storage elements. For subsystem 1, the state-space equations are given by:

$$\begin{pmatrix} \dot{q}_1 \\ \dot{p}_1 \end{pmatrix} = \begin{pmatrix} -1/\tau & 1/I \\ -1/C & -2\zeta\omega_0 \end{pmatrix} \begin{pmatrix} q_1 \\ p_1 \end{pmatrix} + \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix} \begin{pmatrix} e_0 \\ f_2 \end{pmatrix} \quad (1)$$

where  $\omega_0 = 1/\sqrt{IC}$ ,  $\zeta = r/(2\omega_0 I)$  and  $\tau = 1/(RC)$  are the usual reduced parameters of a first degree of freedom linear system, and  $e_0, f_2$  are respectively the effort source of the left subsystem, and the flow source of the right subsystem. The output relation of subsystem 1 provides the effort  $e_1$  associated with the capacitive element:

$$e_1 = \begin{pmatrix} 1/C & 0 \end{pmatrix} \begin{pmatrix} q_1 \\ p_1 \end{pmatrix} + \begin{pmatrix} 0 & 0 \end{pmatrix} \begin{pmatrix} e_0 \\ f_2 \end{pmatrix} \quad (2)$$

For subsystem 2, it yields:

$$\begin{pmatrix} \dot{q}_2 \\ \dot{p}_2 \end{pmatrix} = \begin{pmatrix} -1/\tau & 1/I \\ -1/C & -2\zeta\omega_0 \end{pmatrix} \begin{pmatrix} q_2 \\ p_2 \end{pmatrix} + \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix} \begin{pmatrix} e_1 \\ f_3 \end{pmatrix} \quad (3)$$

where  $f_3$  is the flow source on the right of subsystem. The corresponding output relation gives the flow  $f_2$  that is also the input of subsystem 1:

$$f_2 = \begin{pmatrix} 0 & 1/I \end{pmatrix} \begin{pmatrix} q_2 \\ p_2 \end{pmatrix} + \begin{pmatrix} 0 & 0 \end{pmatrix} \begin{pmatrix} e_1 \\ f_3 \end{pmatrix} \quad (4)$$

For any subsystem, defined by equations (1) or (3), and provided that the damping parameters  $\zeta$  and  $1/\tau$  are small, the eigenvalues of the Jacobian matrix are

given by

$$\lambda_i = -\zeta\omega_0 \left(1 + \frac{1}{2\zeta\omega_0\tau}\right) \pm j\omega_0 \sqrt{1 - \zeta^2 \left(1 - \frac{1}{2\zeta\omega_0\tau}\right)^2} \quad \text{for } i = 1, 2 \quad (5)$$

whereas the eigenvalues of the whole system obtained by coupling the equations (1) and (3) through the output relations (2) and (4) are given by

$$\lambda_i = -\zeta\omega_0 \left(1 + \frac{1}{2\zeta\omega_0\tau}\right) \pm j\omega_0 \sqrt{\phi_i^2 - \zeta^2 \left(1 - \frac{1}{2\zeta\omega_0\tau}\right)^2} \quad \text{for } i = 1, 2 \quad (6)$$

where  $\phi_i^2 = \frac{3 \pm \sqrt{5}}{2}$  are the coupling coefficients. The non-unity ratio  $\frac{\phi_1}{\phi_2} = \sqrt{\frac{3+\sqrt{5}}{3-\sqrt{5}}} \neq 1$  expresses the fact that the two subsystems are strongly coupled and that part of the dynamics lie in the coupling itself.

### 2.3 Analysis of the co-simulated system

The nonlinear hydraulic system of figure 2 being partitioned in the two subsystems shown on 5, the resulting coupled system is co-simulated by assigning to each subsystem a slave simulator which embeds a numerical solver. With the explicit modular stepping shown on figure 1, the output variables of each subsystem  $e_1$  and  $f_2$  are sampled at the communication points  $t_k$ , and are taken as input variables which are held constant on the duration  $H_k$  of the macro-step.

Based on the eigenvalues (6), it should be possible to schedule the macro-steps  $(H_k)_{k=0, \dots, M-1}$ . A first approach consists in choosing a step size smaller than the Nyquist frequency, i.e. half the smallest time constant of the system, in order to ensure a proper sampling of

Figure 5: Sketch of the two nonlinear hydraulic subsystems being co-simulated within LMS Imagine.Lab AMESim. Blocks labeled *SHM* and *shm* are used for exchanging the coupling variables at the scheduled communication points. *SHM* stands for master simulator, whereas *shm* identifies the slave simulator.

the coupling variables:

$$H_k \leq \frac{\pi}{\max_{i=1,2} |\lambda_i|}$$

Unfortunately, this bound is too high regarding stability. This can be shown empirically by performing co-simulation with macro step sizes slightly smaller than the Nyquist bound (about one tenth of the above limit period, for small damping factors of less than 1 %). In a few macro-steps, instabilities propagate between the two subsystems that rapidly lead to divergence. To understand this phenomena and be able to correctly schedule the macro step size, it is necessary to fully analyze the stability of the system with coupling variables subjected to a zero-order sample and hold process, as shown on figure 6.

Stability analysis of this type of loop sampled system is carried by following the methodology described in [8]. This analysis, which focuses on the discretization of the coupling variables induced by the stepping, relies in other respects on the assumption that the subsystems can be exactly integrated by their respective numerical solvers<sup>2</sup>. Since there are only two subsystems connected through a unique loop, the analysis is done by considering the discrete-time transfer function associated with any of the two coupling variables which are obtained from the linearized<sup>3</sup> state-space

<sup>2</sup>or at least that these variable-step solvers are able to bound the truncation errors by any arbitrary tolerance

<sup>3</sup>around the same operating point reached in  $0.5 \leq t < 1$

Figure 6: Bloc diagram of co-simulated system.  $H$  is the length of the current macro-step.

system (1)(2)

$$e_1(z) = -Z \left[ \frac{1-e^{-Hs}}{s} \frac{G_1(s)}{C} \right] f_2(z) + Z \left[ \frac{\omega_0^2 G_1(s)}{s + \alpha_1} e_0(s) \right] \quad (7)$$

or (3)(4)

$$f_2(z) = Z \left[ \frac{1-e^{-Hs}}{s} \frac{G_2(s)}{I} \right] e_1(z) + Z \left[ \frac{\omega_0^2 G_2(s)}{s + \alpha_2} f_3(s) \right] \quad (8)$$

with

$$G_i(s) = \frac{s + \alpha_i}{(s + \alpha_1)(s + \alpha_2) + \omega_0^2}$$

and

$$\alpha_1 = 2\zeta\omega_0, \quad \alpha_2 = 1/\tau$$

By combining the transfer functions (7)(8) and noticing that  $z = e^{Hs}$  by definition, the closed-loop transfer function is given by:

$$(1 + G^*(z)) e_1(z) = \omega_0^2 Z \left[ \frac{G_1(s)}{s + \alpha_1} e_0(s) \right] - \frac{\omega_0^2}{C} G_1^*(z) Z \left[ \frac{G_2(s)}{s + \alpha_2} f_3(s) \right] \quad (9)$$

in which

$$G_i^*(z) = (1 - z^{-1}) Z \left[ \frac{G_i(s)}{s} \right] \quad (10)$$

and

$$G^*(z) = \omega_0^2 G_1^*(z) G_2^*(z) \quad (11)$$

is the open loop discrete-time transfer function. Without giving here all the details about the calculation of (10) obtained using tables of Z-transforms, the Nyquist criterion [6] can be applied on the open loop transfer function (11) to evaluate the stability.

For given values of the reduced parameters, for example  $\zeta = 0.1\%$ , and  $\omega_0 \tau = 0.5$ , the Nyquist plot (figure 7) shows that the system is unstable for macro-step sizes such that  $H \frac{\omega_0 \phi_1}{\pi} \simeq 0.1$ .

Figure 7: (top) Nyquist plot of the open loop transfer function for  $\zeta = 0.1\%$ ,  $\omega_0 \tau = 0.5$ , and  $H \simeq 0.1 \pi / \omega_0 \phi_1$ , which is a ten times oversampling of the Nyquist frequency. (bottom) Zoom on the unit circle showing the encirclement of the -1 point by the  $z = e^{j\omega H}$  contour for  $0 \leq \omega H \leq \pi$

With the same values of the damping parameters, it can be shown that the absolute stability limit is reached for  $H \frac{\omega_0 \phi_1}{\pi} \simeq 0.01$ , and a phase margin of at least  $2^\circ$  is obtained for a ratio less than 0.002, which means oversampling 500 times the Nyquist frequency. The effect of the damping coefficients on the phase margin is

analyzed on figure 8. This oversampling requirement

Figure 8: Plot of the phase margin versus macro-step size  $H$ , for different values of the the damping factor  $\zeta$  (left), and of the decay time constant  $\tau$  (right).

makes co-simulation unpractical for strongly coupled systems that are lightly damped. Indeed, comparison of the CPU time spent for performing the direct simulation of the continuously coupled system of figure 2, with the time needed for co-simulation with 500 times oversampling, exhibits a large slowdown, as shown on table 1. This is easily explained by looking at the number of micro-steps taken by the numerical solvers (last column of table 1). In the case of continuous simulation, the unique LSODA variable-step solver uses only 26000 steps, taking steps as large as  $76 \mu s$ , which is only a four times oversampling of the Nyquist limit period  $\frac{\pi}{\omega_0 \phi_1}$ . With co-simulation the local numerical solvers used for integrating each subsystem (DOPRI5 variable step solvers) cannot take large steps since the micro-step size is bounded by the macro-step size. It yields a large number ( $2 \times 10^6$ ) of dynamics function evaluation by the two numerical solvers, which is inefficient with respect to the frequencies of the coupled system.

### 3 Implementing the linearly implicit stabilization method

The rationale behind this method is to mitigate the stability-performance trade-off exemplified in the last section, by extending the phase margin. The linearly implicit stabilization method, first described by Arnold [4], makes use of the Jacobian matrices of the subsystems to build reduced linear models of the subsystems in state-space form that are exactly integrated locally in time using an unconditionally stable method. This allows to take relatively large macro-steps, which in

Type of simulation	CPU time [s]	Number of micro-steps	Maximum micro-step size [ $\mu$ s]
Direct simulation with LSODA variable-step solver	< 1	26 000	76
Co-simulation with $H = 1 \mu$ s ( $H \frac{\pi}{\omega_0 \phi 1} = 0.002$ )	70	2 000 000	1

Table 1: Comparison of continuous time simulation with co-simulation

turn do not restrict the size of the micro-steps taken by the embedded numerical solvers.

### 3.1 Description of the method

According to the FMI specification [5] the external representation of a system contained in a slave corresponds to a system of ordinary differential equations. Consequently the mathematical model of the whole coupled system is described by the following set of ODEs:

$$\dot{x}(t) = f(x(t), u(t)) \quad (12)$$

$$y(t) = g(x(t), u(t)) \quad (13)$$

$$u(t) = Ky(t) \quad (14)$$

where  $x(t) = (x_1(t), x_2(t), \dots, x_N(t))$  is the state vector obtained by gathering the state vectors of the  $N \geq 2$  subsystems being involved,  $u(t) = (u_1(t), u_2(t), \dots, u_N(t))$  and  $y = (y_1(t), y_2(t), \dots, y_N(t))$  are the input and output variables of all subsystems.

The third equation, which is not specified in the slave subsystems but in the co-simulation master, is required to close the above system. It defines how the output variables are connected to the input variables through a  $K$  matrix, which verify the following properties:

- it is a square matrix, since it can be assumed with no loss of generality that the output of a subsystem is connected to exactly one input of another subsystem
- the elements of  $K$  take their value in  $\{0, 1\}$
- there is exactly one 1 value per row and column of  $K$

The FMI specification [5] for Co-simulation allows a slave subsystem to expose its Jacobian matrices related to the equations (12-13):

$$\begin{aligned} A &= \nabla_x f(x, u) & B &= \nabla_u f(x, u) \\ C &= \nabla_x g(x, u) & D &= \nabla_u g(x, u) \end{aligned}$$

The linearly implicit stabilization method introduced by Arnold in [4] relies on the following three assumptions:

1. the product  $DK$  is assumed to be nilpotent [3], since the class of co-simulation methods considered here do not take into account algebraic loops on coupling variables
2. Inside a co-simulation macro-step, when  $t \in [t_k, t_k + H_k[$ , part of the system (12-13) can be approximated by a linear time invariant system obtained by linearizing the ODEs and the output relation around the point  $x = x(t_k)$ ,  $u = u(t_k)$
3. The linear approximate system is discretized using either the backward Euler method or the trapezoidal rule [2]

Assumption 2 leads to consider the following linear system:

$$\dot{\xi}(t) = \dot{x}(t_k) + A \xi(t) + B(w(t) - u(t_k)) \quad (15)$$

$$\eta(t) = y(t_k) + C \xi(t) + D(w(t) - u(t_k)) \quad (16)$$

where  $A, B, C, D$  are obtained at  $t = t_k$  and  $\xi, \eta$  and  $w$  are the counterpart of  $x, y$  and  $u$  in the linear system. With this choice of variable, the corresponding initial condition is given by  $\xi(t_k) = 0$ .

The coupling equation (14) is thus rewritten to couple the dynamic system of each subsystem with the approximate linear system, inside a macro-step:

$$u(t) = K \eta(t) \quad (17)$$

$$w(t) = Ky(t) \quad (18)$$

On the duration of a macro-step, the differential algebraic system made of equations (12), (15), (13), (17), (16), (18) holds. As there is no algebraic loop (assumption 1), this DAE can be reduced to a coupled set of ODEs by taking the derivate the last four equations.

Following assumption 3, the ODE (15) is first discretized using one of the two proposed methods:

$$(I - r(t - t_k)A) \xi(t) = (t - t_k) [\dot{x}(t_k) + rB(w(t) - u(t_k))]$$

where  $r$  depends on the discretization method and is either 1 for backward Euler or 0.5 for the trapezoidal rule. This equation provides an estimate for the state vector derivative:

$$\dot{\xi}(t) \simeq \mathcal{A}(t) [\dot{x}(t_k) + rB(w(t) - u(t_k))]$$

as well as for the output relation (16):

$$\begin{aligned} \dot{\eta}(t) &= C \dot{\xi}(t) + D \dot{w}(t) \\ &= C \mathcal{A}(t) [\dot{x}(t_k) + rB(w(t) - u(t_k))] + D \dot{w}(t) \end{aligned} \quad (19)$$

with

$$\mathcal{A}(t) = (I - r(t - t_k)A)^{-1}$$

In order to explicitly take into account the lack of algebraic loop, the equation (18) is approximated using the assumption 2. This means that the inputs  $w$  are obtained from a linear approximation of the outputs  $y$  of the subsystems around the point  $t = t_k$ :

$$w(t) - u(t_k) = K[C(x(t) - x(t_k)) + DK(\eta(t) - y(t_k))]$$

$$\dot{w}(t) = K[C\dot{x}(t) + DK\dot{\eta}(t)]$$

After substituting these two relations into (19) and noticing the nilpotency of  $DK$  due to assumption 1, an explicit differential equation for the outputs  $\eta$  is obtained:

$$\begin{aligned} \dot{\eta}(t) &= C \mathcal{A}(t) \dot{x}(t_k) + DKC f(x(t), K\eta(t)) \\ &+ rC \mathcal{A}(t) BK[C(x(t) - x(t_k)) + DK(\eta(t) - y(t_k))] \end{aligned} \quad (20)$$

The coupling condition (17) applied to (12) finally rewrites as:

$$\dot{x}(t) = f(x(t), K\eta(t)) \quad (21)$$

These two ODE (20) and (21) along with the initial condition  $\eta(t_k) = y(t_k)$  explicitly define the dynamics of the system on the duration of a macro-step  $[t_k, t_{k+1} = t_k + H_k]$ . At the end of the step the outputs are evaluated and propagated among the subsystems using (13):

$$y(t_{k+1}) = g(x(t_{k+1}), K\eta(t_{k+1}))$$

### 3.2 Computational flow

The following notation is introduced to describe the submatrices obtained by restricting to the variables involved in the slave simulator numbered  $s \in \{1, \dots, N\}$ :

- $K_{s,s}$  is the square submatrix of  $K$  obtained by taking the columns corresponding to the output variables of slave  $s$ , and the rows corresponding to the input variables of the other slave simulators that are connected to the outputs of slave  $s$ ;
- $K_{s,\bar{s}}$  is the square submatrix of  $K$  obtained by taking the rows corresponding to the input variables of slave  $s$ , and the columns corresponding to the output variables of the other slave simulators that are connected to the inputs of slave  $s$ .

The computational flow is a two steps process, the first step taking place at the communication point of co-simulation, the second step being the continuous time solving of the coupled DOE system (20)(21) during one co-simulation macro-step.

**At  $t = t_k$ :** The slave subsystem  $s \in \{1, \dots, N\}$  computes:

- the derivative of its state vector

$$\dot{x}_s(t_k) = f_s(x_s(t_k), K_{s,\bar{s}} \eta_{\bar{s}}(t_k))$$

- its outputs

$$y_s(t_k) = g_s(x_s(t_k), K_{s,\bar{s}} \eta_{\bar{s}}(t_k))$$

- the Jacobian matrices

$$\begin{aligned} A_{s,s} &= \nabla_x f_s(x_s(t_k), K_{s,\bar{s}} \eta_{\bar{s}}(t_k)) \\ B_{s,s} &= \nabla_u f_s(x_s(t_k), K_{s,\bar{s}} \eta_{\bar{s}}(t_k)) \\ C_{s,s} &= \nabla_x g_s(x_s(t_k), K_{s,\bar{s}} \eta_{\bar{s}}(t_k)) \\ D_{s,s} &= \nabla_u g_s(x_s(t_k), K_{s,\bar{s}} \eta_{\bar{s}}(t_k)) \end{aligned} \quad (22)$$

- it also provides the updated value  $x_s(t_k)$  of its state vector. If  $k = 0$  this is the global initial condition of (12)
- it receives its inputs and set up the stepwise local initial condition for its extended state:

$$K_{s,\bar{s}} \eta_{\bar{s}}(t_k^+) = K_{s,\bar{s}} y_{\bar{s}}(t_k) \quad (23)$$

**For**  $t_k < t \leq t_{k+1}$ : The slave subsystem  $s \in \{1, \dots, N\}$  solves a subset of the coupled DOE system (20)(21):

$$\dot{x}_s(t) = f_s(x_s(t), K_{s,\bar{s}} \eta_{\bar{s}}(t)) \quad (24)$$

$$K_{s,\bar{s}} \dot{\eta}_{\bar{s}}(t) = \bar{f}_{\bar{s}}(x_s(t), K_{s,\bar{s}} \eta_{\bar{s}}(t), t) \quad (25)$$

where  $\bar{f}_{\bar{s}}$  is evaluated by the master:

$$\begin{aligned} \bar{f}_{\bar{s}}(x_s, K_{s,\bar{s}} \eta_{\bar{s}}, t) = & K_{s,\bar{s}} C_{\bar{s},\cdot} \mathcal{A}(t) \dot{x}(t_k) \\ & + K_{s,\bar{s}} D_{\bar{s},\bar{s}} K_{\bar{s},s} C_{s,s} f_s(x_s, K_{s,\bar{s}} \eta_{\bar{s}}) \\ & + r K_{s,\bar{s}} C_{\bar{s},\cdot} \mathcal{A}(t) B_{\cdot,\bar{s}} K_{\bar{s},s} [C_{s,s} (x_s - x_s(t_k)) \\ & + D_{s,s} K_{s,\bar{s}} (\eta_{\bar{s}} - y_{\bar{s}}(t_k))] \end{aligned} \quad (26)$$

Practically, the derivative of the state vector  $\dot{x}_s$  is provided by the slave to the master, which uses it for evaluating the second term of equation (26) instead of evaluating the function  $f_s$  that appears in the right-hand side of equation (24).

### 3.3 Implementation within the FMI framework

The guiding principle behind the organization of computation is a strict devolution of responsibility between the slaves and the master in the co-simulation process. Each slave FMU is responsible locally for the system being solved and does not have any information about the coupling and the surrounding environment. It is up to the master algorithm to gather and assemble this information from the different slaves and to provide to the slaves ways for evaluating the additional ODE that represent the linearized part of the coupled system. This information is provided partly in the description<sup>4</sup> of the model structure of each slave, and partly at run-time through appropriate functions that evaluate the directional derivatives of the system enclosed in the FMU. With this structure-related information, as well as the variables exchanged at communication like the outputs of the models, state variables and their derivatives, a cooperation between the master simulator and slave simulators can be set up that keep the organization clean from the point of view of computational responsibilities.

In addition, the implementation of the stabilized co-simulation has to be compatible with the classical modular stepping specified by the FMI for Co-simulation [5]. This means that the stabilization method operates only if both the slaves FMU and the

co-simulation master cooperate. If it is not supported by any part of the coupled systems, the classical modular stepping with stepwise extrapolation has to be applied.

On the side of the slave FMU, it is mandatory to first enable the computation of the directional derivatives of all state variables and connected outputs, with respect to all state variables and connected inputs. This is done by declaring the flag *providesDirectionalDerivative* and by implementing the *fmiGetDirectionalDerivatives* function of the FMI specification. Moreover, the stabilization method being a model-based extrapolation, it is not compatible with the optional history-based extrapolation schemes that are allowed by the FMI specification. So the current *canInterpolateInputs* attribute has to be extended to specify which type of extrapolation is actually supported.

The way the slave handles its input variables has to be modified: the input variables that appear in the dynamics equation (24) are now considered as additional state variables, according to equation (25), and the input variables now act as initial conditions (equation (23)) for these state variables. The state vectors to be solved by the numerical integrator embedded in the slave is thus  $(x_s, u_s)$ , where  $u_s$  is actually  $K_{s,\bar{s}} \eta_{\bar{s}}$ , the actual mapping between the outputs  $\eta_{\bar{s}}$  of the linear system and the inputs of the slave being done by the master, since the structural information about connection (i.e. the elements of the  $K$  matrix) is only known by the master simulator.

If the master does not support stabilization, the right-hand side of equation (25) reduces to zero and so the actual inputs of the slave do not vary: a zero-order hold extrapolation is thus performed as defined in the FMI specification when the *canInterpolateInputs* flag is not set. In that case, the inputs of each slave is directly given by the initial condition (23), in which  $y_{\bar{s}}$  are the outputs of the slaves that are fed to the inputs of the slave number  $s$ , through the *fmiGetReal* and *fmiSetReal* functions called by the master simulator at each communication point  $(t_k)_{k=0,\dots,M-1}$ .

On the side of the master simulator, more tasks are required to implement the linearly implicit stabilization method. The master has to set up a callback function that is used to evaluate the dynamics associated with the inputs of the slaves. Before co-simulation, the model structure information of the slaves is used to prepare the matrices and the computations that appear in (26). Then, during co-simulation, these elements are updated at each communication step, through calls to the *fmiGetContinuousStates*, *fmiGetDerivatives* and

<sup>4</sup>stored in the corresponding XML file distributed with the FMU

*fmiGetDirectionalDerivatives* functions. Notice that the first two functions are originally defined only in the *Model Exchange* part of specification, so the Co-simulation specification has to be extended in the future. The same is true about the availability of the callback function associated with relation (26). This function is aimed at being called by the numerical solvers of the slaves, when performing the numerical integration of (24)(25). A proposal for extending the FMI for Co-simulation is to define a function called for example *fmiGetStabilizedInputDerivatives* and having the following arguments:

- the current time of the slave numerical solver at which the right hand side of (26) is desired
- the current value of the additional state variables, i.e. the stabilized inputs  $u_s = K_{s,\bar{s}} \eta_{\bar{s}}$
- the current values of the state variables and state derivatives  $(x_s, f_s(x_s, u_s))$  of the slave
- practically, a reference to the master environment, declared as *componentEnvironment* during instantiation, may be needed to help the master simulator identify the calling slave.

This function should return the vector of derivatives of the stabilized inputs, according to relation (26). It has to be declared by the master environment in the *fmi-CallbackFunctions* argument of the slave instantiation function.

The master algorithm is roughly sketched in Algorithm 1, in which the additional tasks required for stabilization are emphasized.

### 3.4 Test results

The hydraulic test case studied in section 2.1 and composed of two elementary hydraulic systems connected in serie is tested under various conditions of co-simulation:

- Reference implementation : transient simulation of the continuously coupled system, using the LSODA variable-step solver [2]
- Co-simulation with native interfaces in the LMS Imagine.Lab AMESim simulation environment, or through a specially crafted prototype of a master simulator supporting the FMI 2.0 RC1 [5] specification with the proposed extensions described in section 3.3

**Require:**  $N$  slave FMU  $s \in \{1, \dots, N\}$  and a sequence of  $M$  macro-steps  $\{H_0, \dots, H_{M-1}\}$ .

read the model structure description of slaves and create the connection matrix  $K$

instantiate each slave  $s$  and provide to it a callback function  $f_{\bar{s}}$

provide the initial conditions for all slave variables  
initialize the slaves

initialize time  $t = t_0$

**for**  $k = 0$  **to**  $M - 1$  **do**

get the outputs of slaves in  $y$

get the state variables and derivatives  $x_s, \dot{x}_s$  of slaves

get the Jacobian matrices  $A_{s,s}, B_{s,s}, C_{s,s}, D_{s,s}$  of slaves

set the inputs of slaves as  $u = Ky$

perform one macro-step for the slaves from  $t$  up to  $t + H_k$

update time  $t \leftarrow t + H_k$

**end for**

**Algorithm 1:** Master simulator algorithm. Lines in blue correspond to the additional tasks required by the stabilization method.

- Comparison of stabilized co-simulation with explicit modular stepping
- Comparison of a mixed C/Python implementation for the co-simulation master, or «direct» C implementation, both with DOPRI5 variable-step solver for the slave simulators

For comparison purpose, all tests are performed with the same values of the reduced damping coefficients as in section 2.3, namely  $\zeta = 0.1\%$  and  $\omega_0 \tau = 0.5$ . The limit period corresponding to the Nyquist frequency is  $\pi/\omega_0 \phi_1 \simeq 425 \mu\text{s}$ , the absolute stability limit is reached for  $H \simeq 5 \mu\text{s}$ , and a  $2^\circ$  phase margin is obtained for  $H = 1 \mu\text{s}$ .

The test results are summarized in table 2. The accuracy of co-simulation is measured by taking the root mean square error on the coupling variables  $e_1$  and  $f_2$  with respect to the reference implementation and the mixed tolerance for all the variable-step solvers is set to  $10^{-5}$ . In all co-simulation tests, the CPU time is measured by setting the print interval (i.e. the sampling of result variables) to  $50 \mu\text{s}$ , corresponding to the largest macro-step size used across the tests, in order to have comparable processing times regarding result storage and disk access.

The stabilization method allows to choose large macro-step sizes  $H$ , up to the size of the numerical

Tested implementation	Macro-step size $H$ [ $\mu$ s]	RMS error	CPU time [s]
#1. Continuously coupled system with variable step solver in AMESim		<i>reference</i>	1.0
#2. Explicit co-simulation, native AMESim interface	1	104	70.0
#3. Stabilized co-simulation, native AMESim interface	50	207	8.5
#4. FMI 2.0 explicit co-simulation, mixed Python/C prototype	1	123	40.0

#6. FMI 2.0 explicit co-simulation, direct C prototype	1	123	12.0
#7. FMI 2.0 stabilized co-simulation, backward Euler, direct C prototype	50	215	1.5
#8. FMI 2.0 stabilized co-simulation, trapezoidal rule, direct C prototype	50	152	1.5

Table 2: Summary of tests performed with different implementations, macro-step sizes  $H$  and discretization methods.

micro-steps taken by the variable-step solver in the reference case. Indeed, the absolute stability limit of co-simulation seems to be reached for macro-step sizes of about  $76 \mu$ s, which is the maximum numerical step size reported in table 1. Consequently, a maximum value of  $50 \mu$ s is used for comparison across the tests #3, #5, #7 and #8.

Clearly, the performances obtained for the maximum macro step size depend on the implementation. Additional operations are needed by the stabilization method like the computation of Jacobian matrices and integration of the additional state equations related to the inputs on the side of the slaves, and the evaluation of the approximate dynamics (26) on the side of the master. This overhead, if not efficiently implemented, may cancel out the gain over the number of micro-steps. This is the case with the mixed Python/C implementation #5 of the master simulator, which exhibits poor performances with respect to #3, due to the too many context switches between the two environments. On the contrary, the two other C-based implementations #3 and #7 (or #8), show a large speed-up factor of about 8 with respect to the corresponding explicit co-simulations #2 and #6.

Regarding the accuracy, the tests #3, #5 and #7, which are based on a backward Euler method, yield nearly the same level of accuracy, about twice the error obtained with explicit co-simulation at  $H = 1 \mu$ s. The increase of the RMS error with the macro-step size is depicted on figure 9 for tests #7 and #8. Clearly, the use of a second-order method like the trapezoidal rule provides more accurate results, for the same computational load.

Figure 9: RMS errors obtained with respect to continuously coupled simulation versus the macro step size.

## 4 Conclusions

Although co-simulation is generally considered a robust method of simulator coupling, this paper presented the main issue that remains with the co-simulation of strongly coupled system, namely the trade-off between stability (or accuracy) and the computational performances. With the help of a simple yet representative example of this class of system, it showed how the stability issue may affect the computational load, since an oversampling factor as large as 500 is observed with respect to the highest dynamics of the system. The implementation of the linearly implicit stabilization method within the framework of the FMI for Co-simulation 2.0 standard then showed that significant speed-up can be regained at the price of a moderate loss of accuracy, provided that an efficient implementation is available as well as some minor extensions to the FMI for Co-simulation specification. With the advent of the FMI 2.0 specification, which one of its major enhancements is an interface for the directional derivative matrices, it seems that the efficient co-simulation of strongly coupled systems becomes feasible. Although this paper focused on the stabilization of the more common type of co-simulation, i.e. the explicit modular stepping, further performance gains are expected with more advanced types of co-simulation, for instance by combining the stabilization method with variable macro-step size heuristics or implicit (iterative) stepping, since these currently seldom used techniques are now enabled by the FMI specifications.

## Abstract

The growing complexity of systems, together with increasing available parallelism provided by multi-core chips, calls for the parallelization of simulation. Simulation speed-ups are expected from co-simulation and parallelization based on models splitting into loosely coupled sub-systems in the framework of Functional Mockup Interface (FMI). However, slackened synchronization between the sub-models and associated solvers running in parallel introduces integration errors, which must be kept inside predefined bounds. In this paper, context-based extrapolation is investigated to improve the trade-off between integration speed-ups, needing large communication steps, and simulation precision, needing frequent updates for the models inputs. An internal combustion engine, based on FMI for model exchange, is used to assess the parallelization methodology.

## 1 Introduction

During the design process of complex systems, such as in automotive, simulation is proven to be an indisputable step between concept design and prototype validation. Realistic simulations allow for the preliminary evaluation, tuning and possibly redesign of proposed solutions ahead of implementation, thus lowering the risks. To be confident in the result, building such simulations requires high-fidelity models both for the components and for their interaction.

Currently, building high-fidelity system-level models of cyber-physical systems in general and automo-

tive cars in particular, is a challenging duty. One problem is the diversity of models, designed for different environments, provided by various multi-disciplinary teams. Distinctive environments are preferred for a specific use due to specific strengths (modeling language, libraries, solvers, cost...). The FMI specification has been proposed to improve this issue [1].

However, the simulation of high-fidelity models is time consuming, and reaching real-time constraints is out of the capabilities of single-threaded simulations running on single cores. Simulation speed-ups are needed, in particular by splitting the systems into sub-models to be executed in parallel on currently available multi-core chips.

Unfortunately most of the existing simulation software are currently unable to exploit multi-core platforms, as they rely on sequential Ordinary Differential Equations (ODE) and Differential Algebraic Equations (DAE) solvers. The co-simulation approaches can provide significant improvements by allowing to simulate together models coming from different areas, and to validate both the individual behaviors and their interaction [2]. The simulators may be exported from original authoring tools as Functional Mock-up Units (FMUs), and then imported in a co-simulation environment. Hence, they cooperate at run-time, thanks to the FMI definitions of their interfaces, and to the master algorithms of these environments.

The “FMI for model exchange” framework allows for solving independently the sub-models using custom solvers. In this context, several methods have been already proposed to perform real-time distributed simulation of complex physical models. For example, in [3], the study focused on the case of fixed-step solvers. Then, in [4], the study was extended to handle the case of variable time-step solvers.

However, accounting for the dependencies between

the sub-models needs to synchronize them at some time intervals. Certainly, this synchronization avoids the propagation of numerical errors in the simulation results and guarantees their correctness. Unfortunately, these synchronization constraints also lead to waiting periods and idle time of some processors. Consequently it decreases the potential efficiency of the threaded parallelism existing in multi-core platforms.

To overcome this limitation, and to more efficiently exploit the available parallelism, the dependencies constraints should be relaxed as far as possible while keeping accumulated errors under control. In a first step, this can be performed by a well done system decomposition that minimizes the dependencies between the sub-models. For example, a method was proposed in [5] for distributed simulation using a technology based on bilateral delay lines called transmission line modeling (TLM), where the decoupling point is chosen when the variables change slowly and the time-step of the solver is relatively small.

Unfortunately, most often perfect decoupling cannot be reached and data dependencies still exist between parallel blocks. Some synchronization between them must be kept tight through small communication steps between models, which prevents the variable time-step solvers to reach large integration steps.

It is proposed that the synchronization steps can be stretched out with limited deterioration of the simulation precision, thanks to a well-suited, albeit simple, context-based polynomial extrapolation of the exchanged data beyond the synchronization points between sub-models.

This paper is organized as follows. First, a formal model of a hybrid dynamical system is given and a model of the integration errors due to slack synchronization is sketched in Section 2. The background on prediction and polynomial prediction algorithms are developed in Section 3. The principles for context-based extrapolation, to cope with the hybrid nature of the models, are exposed in Section 4. The methodology is assessed in Section 5 using the model of an internal combustion engine.

## 2 Motivation for extrapolation

### 2.1 Model formalization

Consider a hybrid dynamical system  $\Sigma$  described by a set of nonlinear differential equations:

$$\begin{aligned}\dot{\mathbf{X}} &= \mathbf{f}(t, \mathbf{X}, \mathbf{D}, \mathbf{U}) \quad \text{for } t_n \leq t < t_{n+1}, \\ \mathbf{Y} &= \mathbf{g}(t, \mathbf{X}, \mathbf{D}, \mathbf{U}),\end{aligned}$$

where  $\mathbf{X} \in \mathbb{R}^{n_x}$  is the continuous state vector,  $\mathbf{D} \in \mathbb{R}^{n_d}$  is the discrete state vector,  $\mathbf{U} \in \mathbb{R}^{n_u}$  is the input vector,  $\mathbf{Y} \in \mathbb{R}^{n_y}$  is the output vector and  $t \in \mathbb{R}^+$  is the time.

The sequence  $(t_n)_{n \geq 0}$  of strictly increasing time instants represents discontinuity points called “state events”, which are the roots of the equation

$$h(t, \mathbf{X}, \mathbf{D}, \mathbf{U}) = 0.$$

The function  $h$  is usually called zero-crossing function or event indicator. It is used for *event detection* and *location* [6].

At each time instant  $t_n$ , a new continuous state vector can be computed as a result of the *event handler*

$$\mathbf{X}(t_n) = \mathbf{I}(t_n, \mathbf{X}, \mathbf{D}, \mathbf{U}),$$

and a new discrete state vector can be computed as a result of discrete state update

$$\mathbf{D}(t_n) = \mathbf{J}(t_{n-1}, \mathbf{X}, \mathbf{D}, \mathbf{U}).$$

If no discontinuity affects a component of  $\mathbf{X}(t_n)$ , the right limit of this component will be equal to its value at  $t_n$ .

It is assumed that  $\Sigma$  is well posed in the sense that a unique solution exists for each admissible initial conditions  $\mathbf{X}(t_0)$  and  $\mathbf{D}(t_0)$  and that consequently  $\mathbf{X}$ ,  $\mathbf{D}$ ,  $\mathbf{U}$ , and  $\mathbf{Y}$  are piece-wise continuous functions in  $[t_n, t_{n+1}]$ .

To execute the system in parallel, the model must be split into several sub-models. Assume for simplicity, that the system is decomposed into two subsystems as in Figure 1. Our approach generalizes to any decomposition into  $N$  blocks of system  $\Sigma$ .

Therefore, the system can be written as:

$$\begin{cases} \dot{\mathbf{X}}_1 = \mathbf{f}_1(\mathbf{X}_1, \mathbf{X}_2, \mathbf{D}_1, \mathbf{U}_1) \\ \mathbf{Y}_1 = \mathbf{g}_1(\mathbf{X}_1, \mathbf{X}_2, \mathbf{D}_1, \mathbf{U}_1) \end{cases} \text{ and } \begin{cases} \dot{\mathbf{X}}_2 = \mathbf{f}_2(\mathbf{X}_1, \mathbf{X}_2, \mathbf{D}_2, \mathbf{U}_2) \\ \mathbf{Y}_2 = \mathbf{g}_2(\mathbf{X}_1, \mathbf{X}_2, \mathbf{D}_2, \mathbf{U}_2) \end{cases}$$

with  $\mathbf{X} = [\mathbf{X}_1 \ \mathbf{X}_2]^T$  and  $\mathbf{D} = [\mathbf{D}_1 \ \mathbf{D}_2]^T$ , where  $^T$  denotes the matrix transpose.

Here,  $\mathbf{U}_1$  are the inputs needed for  $\Sigma_1$  and  $\mathbf{U}_2$  are the inputs needed for  $\Sigma_2$ . In other words,  $\mathbf{U}_1 \cup \mathbf{U}_2 = \mathbf{U}$

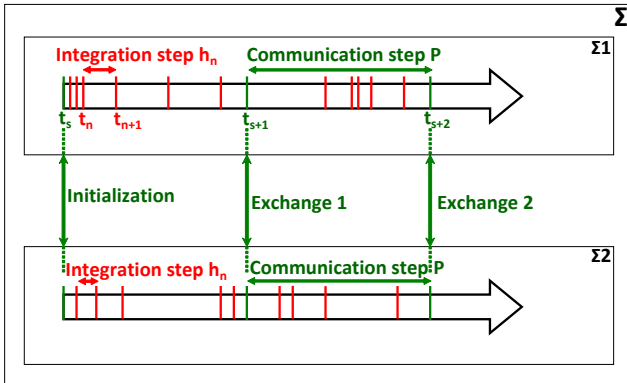

Figure 1: System splitting for parallelization.

and  $U_1 \cap U_2$  can be an empty set or not according to the achieved decoupling.

In the same way,  $Y_1$  are the outputs produced by  $\Sigma_1$  and  $Y_2$  are the outputs produced by  $\Sigma_2$ . In other words,  $Y_1 \cup Y_2 = Y$  and  $Y_1 \cap Y_2 = \emptyset$ .

To perform the numerical integration of the whole multivariable system, each of these simulators needs to exchange, at communication points, the data needed by the others (see Figure 2). To speed up the integration, the parallel branches must be as independent as possible, so that they are synchronized at a rate  $P$  by far slower than their internal integration step  $h_n$  ( $P \gg h_n$ ). Therefore, between communication points, each simulator integrates at its own rate (assuming a variable step solver), and considers that the data incoming from others simulators is hold as constant.

Figure 2:  $\Sigma$  split into  $\Sigma_1$  and  $\Sigma_2$  for parallel simulation.

It is likely that large communication intervals allow to speed up the numerical integration, but may result in integration errors and poor confidence in the final result. Modeling the errors induced by slack synchronization is a first step to find effective directions to improve the trade-offs between integration speed and accuracy.

## 2.2 Integration errors and parallelism

To compute the next state value  $X_i(t_{n+1})$ ,  $i = 1, 2$  (see Figure 3), the numerical solver needs at least the values of  $X_i(t_n)$  and  $\dot{X}_i(t_n) = f_i(X(t_n))$  (e.g. for Euler

integration). The inputs and discrete states are omitted for clarity.

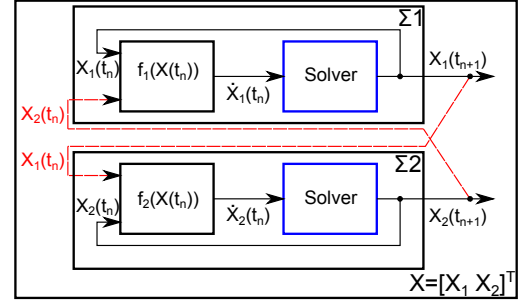

Figure 3: System's internal composition.

When computing  $\dot{X}_1(t_n) = f_1(X(t_n))$ , the value of the local variable  $X_1(t_n)$  is always available. This is not the case for  $X_2(t_n)$ , which is computed in a parallel branch. In fact,  $X_2$  is only available in branch 1 at synchronization with interval  $P$ , which is larger than the integration step  $h_n$ . In other words,  $X_2(t_n)$  is available only when the time  $t_n$  corresponds with a synchronization point  $t_s$  (see Figure 2), otherwise its estimated value is the one transmitted at the previous synchronization point. Let us evaluate the evolution of integration errors due to slack synchronization between the parallel branches when computing  $\dot{X}_1(t_n) = f_1(X(t_n))$ . The analysis on  $\Sigma_1$  remains valid for  $\Sigma_2$ .

The influence of using a delayed value of  $X_2$  in  $f_1(\cdot)$  (respectively  $X_1$  in  $f_2(\cdot)$ ) is due to the lack of updated data during a delay  $\tau$ , represented by the difference between the current integration time  $t_n$  and the last synchronization time  $t_s$  as

$$\tau = t_n - t_s \quad (1)$$

with

$$t_s = P \left\lfloor \frac{t_n}{P} \right\rfloor$$

therefore

$$t_s = \begin{cases} lP & \text{when } t_n = lP \quad l \in \mathbb{N}^* \\ (l-1)P & \text{when } t_n < lP \quad l \in \mathbb{N}^* \end{cases}$$

leading to

$$\begin{cases} \tau = 0 & \text{when } t_n = t_s \\ \tau > 0 & \text{when } t_n > t_s \end{cases}$$

Therefore, the induced error at  $t_{n+1}$  in the subsystem  $\Sigma_1$ , denoted  $E_1(t_{n+1})$ , is the difference between  $X_1(t_{n+1})$  for the unsplit model (2) and  $\tilde{X}_1(t_{n+1})$  for the split model (3):

$$\mathbf{X}_1(t_{k+1}) = \mathbf{X}_1(t_k) + h_k \mathbf{f}_1(\mathbf{X}_1(t_k), \mathbf{X}_2(t_k)), \quad k \in \{0, \dots, n\} \quad (2)$$

$$\tilde{\mathbf{X}}_1(t_{k+1}) = \begin{cases} \mathbf{X}_1(t_{k+1}) & k=0 \\ \tilde{\mathbf{X}}_1(t_k) + h_k \mathbf{f}_1(\tilde{\mathbf{X}}_1(t_k), \tilde{\mathbf{X}}_2(t_k - \tau)) & k \geq 1 \end{cases} \quad (3)$$

In other words,

$$\begin{aligned} \mathbf{E}_1(t_{n+1}) &= \sum_{k=0}^n \mathbf{E}_1(t_k) \\ &\quad + h_n [\mathbf{f}_1(\mathbf{X}_1(t_n), \mathbf{X}_2(t_n)) - \mathbf{f}_1(\tilde{\mathbf{X}}_1(t_n), \tilde{\mathbf{X}}_2(t_n - \tau))] \\ &= \mathbf{E}_{1,p}(t_n) + \mathbf{E}_{1,c}(t_{n+1}) \end{aligned}$$

where

$$\begin{aligned} \mathbf{E}_{1,c}(t_{n+1}) &= h_n [\mathbf{f}_1(\mathbf{X}_1(t_n), \mathbf{X}_2(t_n)) - \mathbf{f}_1(\tilde{\mathbf{X}}_1(t_n), \tilde{\mathbf{X}}_2(t_n - \tau))] \\ \mathbf{E}_{1,p}(t_n) &= \sum_{k=0}^n \mathbf{E}_1(t_k) \end{aligned} \quad (4)$$

Here  $\mathbf{E}_{1,c}(t_{n+1})$  is the current error generated at  $t_{n+1}$  whatever a synchronization or not. So, the global decoupling error  $\mathbf{E}_1(t_{n+1})$  is the result of the accumulation of past errors  $\mathbf{E}_{1,p}(t_n)$  and the current error  $\mathbf{E}_{1,c}(t_{n+1})$ . As a conclusion, to achieve a correct result, two conditions must be met for the current (local) error and the global error:

- $|\mathbf{E}_{1,c}(t_{n+1})| < \epsilon_{\text{loc}}$ : allowed local error
- $|\mathbf{E}_1(t_{n+1})| < \epsilon_{\text{glo}}$ : allowed global error

These conditions can be satisfied by acting on some parameters. Indeed, in (4), the delay error depends on the integration steps  $h_n$  and on the delay  $\tau$ . The integration step  $h_n$  is already adapted following the numerical solver strategy and the user-defined solver tolerance. The delay  $\tau$ , however, depends on the last synchronization time  $t_s$ , which is function of the synchronization period  $P$ .

The delay induced error tends to zero when the delay  $\tau$  tends to zero, which means that the delay error can be eliminated with the synchronization interval set equal to the integration steps. In other words, all the parallel subsystems should be integrated at the same adaptive rate (in the case of adaptive synchronization period), or with same fixed time-step. These two assumptions are very restrictive, as they force to choose a global adequate time-step regardless the discontinuities and the stiffness of the sub-systems. Compared with the single-threaded simulation, the only possible speed-ups during a parallel execution would be brought by the brute force computation power of the multicore machine, reduced by the parallelization cost.

Therefore, considering a split model and a parallel execution, a trade-off must be found between acceptable simulation errors, thanks to tight enough synchronization, and simulation speed-ups thanks to decoupling between sub-models.

To add a degree of freedom to this trade-off achievement, we propose to extrapolate model inputs to compensate the stretching out of the communication steps between sub-models. Note that in this first approach of the polynomial extrapolation, the synchronization interval is considered as constant. Future enhancements will consider communication step size control, for which the error analysis and estimation can be inspired by [7]. Extrapolation is sensitive for different reasons:

- prediction should be efficient: causal, sufficiently fast and reliable;
- there exist no universal prediction scheme, efficient with every signal;
- polynomial prediction may fail in stiff cases [8] (cf. Section 4 for details).

We choose to base our extrapolation on polynomial prediction, which allows fast and causal calculations. The rationale is that, in this situation, the computing cost of a low-order polynomial predictor would be by far smaller than the extra model computations needed by shorten communication steps. Since such predictions would be accurate neither for any signal (for instance, blocky versus smooth signals) nor any signal behavior (slow variations versus steep onsets), we borrow a context-based approach, common with lossless image coders [9], such as GIF or PNG formats. The general aim of these image coders is to predict a pixel value based on a pattern of causal neighboring pixels. Compression is obtained when the prediction residues possess smaller intensity values, and more generally a better distribution (concentrated around close-to-zero values) than the pixels in the original image. They may thus be coded on smaller “bytes”, using entropy coding techniques. In images, one distinguishes basic “objects” such as smooth-intensity varying regions, or edges with different orientations. Based on simple calculation of the prediction pattern pixels, different contexts are inferred (e.g. flat, smooth,  $+45^\circ$  or  $-45^\circ$  edges, etc.). Look-up table predictors are then used, depending on the context.

In the proposed approach, we build a heuristic table of contexts (in Section 4) based on a short frame of past samples, and affect a pre-determined polynomial

predictor to obtain a context-dependent extrapolated value. We now review the principles of extrapolation.

### 3 Causal polynomial prediction

#### 3.1 Background on prediction

This section is dedicated to a peculiar instance of discrete time series, or signal, forecasting. The neighboring topics of prediction or extrapolation represent a large body of knowledge in signal processing [10], econometrics [11] or control [12].

In the present case, we consider a real-valued, regularly sampled signal  $u$ , with period  $P$ , known at synchronization or communication intervals. Prediction in general assumes the knowledge of signal formation models. Since very little is assumed on the signal's dynamics (no behavioral/explicit model is available, periodicity and regularity are unknown), and as we operate under real-time conditions, implying strong causality, only a tiny fraction of time series methods are practically applicable. Zeroth-order hold or nearest-neighbor extrapolation is probably the most natural, the less hypothetical, and the less computationally expensive forecasting method. It consists in using the latest known sample as the predicted value. It possesses small (cumulative) errors when the time series is relatively flat or its sampling rate is sufficiently high, with respect to the signal's dynamics. In other words, it is efficient when the time series is sampled fast enough to ensure small variations between two consecutive sampling times. However, it indirectly leads to under-sampling related disturbances, that affect the signal content. They appear as quantization-like noise, offset or peak flattening.

In our co-simulation framework, communication intervals are not chosen arbitrarily small for computational efficiency. Thus, the slow variation of inputs and outputs cannot be ensured in practice. Hence, borrowing additional samples from the past known data and using higher-order extrapolation methods could be beneficial, provided a trade-off of cost and error is met. Different forecast methods of various fidelity and complexity may be efficiently evaluated. We focus here on polynomial methods, for their simplicity and ease of implementation, following initial works in [13, Chapter 16].

#### 3.2 Notations

We denote by  $P_{(\delta,\lambda)}$  the least-squares polynomial predictor of degree  $\delta \in \mathbb{N}$  and prediction length  $\lambda \in \mathbb{N}^*$ .

The prediction length  $\lambda$  represents the number of past samples required for each prediction, performed in the least-squares sense [14, p. 227 sq.]. For convenience, we use a 0-last-sample-index convention: we re-index the frame of the  $\lambda$  past samples such that the last known sample is indexed by 0. Computations for the prediction at relative time  $\tau$  (loosely denoted by  $u(\tau)$ ), defined in (1), thus require past samples  $\{u_{1-\lambda}, u_{2-\lambda}, \dots, u_0\}$ . We first recall principles and formulas for a standard least-squares, degree-two or parabolic prediction. The general equations are derived next.

#### 3.3 Polynomial prediction of degree $\delta = 2$

We look for the best fitting parabola, i.e. with degree  $\delta = 2$ ,  $u(t) = a_\delta + a_{\delta-1}t + a_{\delta-2}t^2$  to approximate the set of discrete samples  $\{u_{1-\lambda}, u_{2-\lambda}, \dots, u_0\}$ . The prediction polynomial  $P_{(2,\lambda)}$  is defined by the vector of polynomial coefficients  $\mathbf{a} = [a_2, a_1, a_0]^T$ . They are determined, in the least-squares sense [15], by minimizing the squared or quadratic, error:

$$e(\mathbf{a}) = \sum_{l=1-\lambda}^0 (u_l - (a_2 + a_1 l + a_0 l^2))^2.$$

Note that the  $l$  indices here are non-positive, between  $1 - \lambda$  and 0. The minimum error is obtained by solving the following system of equations (zeroing the derivatives with respect to each of the free variables  $a_i$ ):

$$\forall i \in \{0, 1, 2\}, \quad \frac{\partial e(\mathbf{a})}{\partial a_i} = 0$$

namely:

$$\begin{cases} \sum_{l=1-\lambda}^0 l^0 (u_l - (a_2 l^0 + a_1 l^1 + a_0 l^2)) = 0, \\ \sum_{l=1-\lambda}^0 l^1 (u_l - (a_2 l^0 + a_1 l^1 + a_0 l^2)) = 0, \\ \sum_{l=1-\lambda}^0 l^2 (u_l - (a_2 l^0 + a_1 l^1 + a_0 l^2)) = 0. \end{cases} \quad (5)$$

The system in (5) may be rewritten as:

$$\begin{cases} \sum_{l=1-\lambda}^0 u_l = a_2 \sum_{l=1-\lambda}^0 l^0 + a_1 \sum_{l=1-\lambda}^0 l^1 + a_0 \sum_{l=1-\lambda}^0 l^2, \\ \sum_{l=1-\lambda}^0 l u_l = a_2 \sum_{l=1-\lambda}^0 l^1 + a_1 \sum_{l=1-\lambda}^0 l^2 + a_0 \sum_{l=1-\lambda}^0 l^3, \\ \sum_{l=1-\lambda}^0 l^2 u_l = a_2 \sum_{l=1-\lambda}^0 l^2 + a_1 \sum_{l=1-\lambda}^0 l^3 + a_0 \sum_{l=1-\lambda}^0 l^4. \end{cases}$$

Let  $m^d = \sum_{l=0}^{\lambda-1} l^{\delta-d} u_{-l}$  (here the indices  $l$  are positive) denote the  $(\delta-d)$ -th moment of the frame  $u_i$ , and  $\mathbf{m}$  the vector of moments  $[m^2, -m^1, m^0]^T$ . We express the sums of integer powers by  $\Sigma_\lambda^d = \sum_{i=0}^{\lambda-1} i^d$ . Closed-form expressions exist for  $\Sigma_\lambda^d$ , involving Bernoulli sequences [16]. For instance:

- $\Sigma_\lambda^0 = \lambda$ ,
- $\Sigma_\lambda^1 = (\lambda-1)\lambda/2$ ,
- $\Sigma_\lambda^2 = (\lambda-1)\lambda(2\lambda-1)/6$ ,
- $\Sigma_\lambda^3 = (\lambda-1)^2\lambda^2/4$ ,
- $\Sigma_\lambda^4 = (\lambda-1)\lambda(2\lambda-1)(3\lambda^2-3\lambda-1)/30$ .

We now form the matrix  $\mathbf{Z}_{(2,\lambda)}$  of sums of powers (depending on  $\delta = 2$  and  $\lambda$ ):

$$\mathbf{Z}_{(2,\lambda)} = \begin{bmatrix} \Sigma_\lambda^0 & -\Sigma_\lambda^1 & \Sigma_\lambda^2 \\ -\Sigma_\lambda^1 & \Sigma_\lambda^2 & -\Sigma_\lambda^3 \\ \Sigma_\lambda^2 & -\Sigma_\lambda^3 & \Sigma_\lambda^4 \end{bmatrix}.$$

The system in (5) rewrites:

$$\begin{bmatrix} m^2 \\ -m^1 \\ m^0 \end{bmatrix} = \begin{bmatrix} \Sigma_\lambda^0 & -\Sigma_\lambda^1 & \Sigma_\lambda^2 \\ -\Sigma_\lambda^1 & \Sigma_\lambda^2 & -\Sigma_\lambda^3 \\ \Sigma_\lambda^2 & -\Sigma_\lambda^3 & \Sigma_\lambda^4 \end{bmatrix} \times \begin{bmatrix} a_2 \\ a_1 \\ a_0 \end{bmatrix}$$

or  $\mathbf{m} = \mathbf{Z}_{(2,\lambda)} \times \mathbf{a}$ . Now we want to find the value predicted by  $P_{(2,\lambda)}$  at time  $\tau$ . Let  $\boldsymbol{\tau}_2 = [1, \tau, \tau^2]^T$  be a vector of  $\tau$  powers. Then  $u(\tau)$  is equal to  $a_2 + a_1\tau + a_0\tau^2 = \boldsymbol{\tau}_2^T \times \mathbf{a}$ . Finally,  $\mathbf{Z}_{(2,\lambda)}$  is always invertible, provided that  $\lambda > \delta$ . Its inverse is denoted  $\mathbf{Z}_{(-2,\lambda)}$ . It thus does not need to be updated in real-time. It may be computed off-line, numerically or even symbolically. Hence:

$$u(\tau) = (\boldsymbol{\tau}_2^T \times \mathbf{Z}_{(-2,\lambda)}) \times \mathbf{m}.$$

The vector  $\boldsymbol{\tau}_2$  and  $\mathbf{Z}_{(-2,\lambda)}$  are fixed, and the product  $\boldsymbol{\tau}_2^T \times \mathbf{Z}_{(-2,\lambda)}$  may be stored at once. Thus, for each prediction, the only computations are the update of the vector  $\mathbf{m}$  and his product with the aforementioned stored matrix. It thus enables look-up-table-based predictions, which helps to reduce propagation errors in matrix computations.

### 3.4 General formulas

Inferring from the previous example, we easily get a more generic extrapolation pattern in its matrix form:

$$u(\tau) = \begin{bmatrix} 1 & \tau & \dots & \tau^\delta \end{bmatrix} \times \begin{bmatrix} \Sigma_\lambda^0 & -\Sigma_\lambda^1 & \dots & (-1)^\delta \Sigma_\lambda^\delta \\ -\Sigma_\lambda^1 & \ddots & \ddots & \vdots \\ \vdots & \ddots & \ddots & \vdots \\ (-1)^\delta \Sigma_\lambda^\delta & \dots & \dots & \Sigma_\lambda^{2\delta} \end{bmatrix}^{-1} \times \begin{bmatrix} m^\delta \\ -m^{\delta-1} \\ \vdots \\ (-1)^\delta m^0 \end{bmatrix}.$$

Note  $\boldsymbol{\tau}_\delta = [1, \tau, \dots, \tau^\delta]^T$ , then:

$$u(\tau) = \boldsymbol{\tau}_\delta^T \mathbf{Z}_{(-\delta,\lambda)} \mathbf{m}.$$

As in the previous case, only  $\mathbf{m}$  and one matrix product need be computed in real-time. When  $\delta = 0$ , one easily sees that:

$$u(\tau) = \frac{m^0}{\Sigma_\lambda^0} = \frac{u_{1-\lambda} + \dots + u_0}{\lambda},$$

that is, the running average of past frame values, reducing to the zeroth-order hold when  $\lambda = 1$ . Although the matrix formulation is convenient, actual computation does not require true matrix calculus, especially for small degrees  $\delta$ . For instance,  $P_{(1,3)}$  yields the simple estimator form:  $u(\tau) = \frac{\tau}{2}(u_0 - u_{-2}) + \frac{1}{6}(5u_0 + 2u_{-1} - u_{-2})$ .

## 4 Context-based extrapolation

Actual complex systems usually present nonlinearities and discontinuities, so that it is hard to predict their future behavior from past observations. Moreover the considered models are generated using the FMI for model exchange framework, which does not provide the inputs' derivatives (conversely with the FMI for co-simulation architecture). Hence the previously described polynomial prediction cannot correctly extrapolate along all the system trajectories.

For example, [17] studies a method based on a sequential implementation of continuous dynamical systems that uses a constant, linear or quadratic extrapolation and a linear interpolation to improve the accuracy of the modular time integration. The study shows that the method is successful for non-stiff systems and it

fails for the stiff case. The context-based extrapolation is then performed to account for steps, stiffness, discontinuities or weird behavior, and use adapted extrapolation to limit excessively wrong prediction.

Keeping with the previous 0-last-sample-index convention, and for the sake of simplicity, we first define a measure of variation based on the last three samples:  $d_0 = u_0 - u_{-1}$  and  $d_1 = u_{-1} - u_{-2}$ , the last and previous differences. Their absolute values are compared with two thresholds,  $\gamma_0$  and  $\gamma_{-1}$ , respectively. We then define three complementary conditions:

- $O$  if  $|d_i| = 0$ ;
- $C_i$  if  $0 < |d_i| \leq \gamma_i$ ;
- $\overline{C}_i$  if  $|d_i| > \gamma_i$ ;

We can now define the six-context Table 1, and examples for their associated heuristic polynomial predictors. The six contexts form a partition, i.e. they are mutually exclusive, and cover all possible options for a hybrid dynamical system. They are illustrated in Figure 4. Their names represent their behavior. For instance, the flat context addresses steady signals, for which a mere zeroth-order hold suffices, hence  $P_{(0,1)}$ . The calm context represents a sufficiently sampled situation, where value increments over time remain below fixed thresholds. In this case, the signal is relatively regular, and could be approximated by a quadratic polynomial, for instance  $P_{(2,5)}$ . For the “flat” and “jump” contexts, there is an additional procedure which consists in resetting the extrapolation to prevent inaccurate prediction. For example, when context 1 is chosen just after context 5, the quadratic extrapolation  $P_{(2,5)}$  requires 5 valid samples, whereas the last 3 only are relevant.

Our two-threshold is relatively simple. Hence, the choice of the thresholds  $\gamma_0$  and  $\gamma_{-1}$ , is potentially crucial. For instance, fixed values may reveal inefficient under important amplitude or scale variation of signal. Hence, we have chosen here to compute them, in a running manner, on the past frame  $\{u_{1-\omega}, \dots, u_{-3}\}$ . With excessively low thresholds, high-order extrapolations would be rarely chosen, loosing the benefits of predictions. Too high thresholds would in contrast suffer from any unexpected jump or noise. As the contexts are based on backward derivatives, we have used in the simulations presented here the mid-range statistical estimator of their absolute values. This amounts to set:  $\gamma_0 = \gamma_{-1} = \frac{1}{2} \max_{i \in [1-\omega, \dots, -3]} (|u_i - u_{i+1}|)$ .

Table 1: Summary of the six-context Table.

n(ame)	#	$ d_{-2} $	$ d_{-1} $	$d_{-2} \cdot d_{-1}$	$(\delta, \lambda)$
f(lat)	0	$O$	$O$	$O$	$(0, 1)$
c(alm)	1	$C_1$	$C_2$	any	$(2, 5)$
m(ove)	2	$\overline{C}_1$	$\overline{C}_2$	any	$(0, 1)$
r(est)	3	$\overline{C}_1$	$C_2$	any	$(0, 2)$
t(ake)	4	$\overline{C}_1$	$\overline{C}_2$	$> 0$	$(1, 3)$
j(ump)	5	$\overline{C}_1$	$\overline{C}_2$	$< 0$	$(0, 1)$

## 5 Case study

### 5.1 Engine simulator

In this study, a Spark Ignition (SI) RENAULT F4RT engine has been modeled. It is a four-cylinder in-line Port Fuel Injector (PFI) engine in which the engine displacement is  $2000\text{cm}^3$ . The air path (AP) consists in a turbocharger with a mono-scroll turbine controlled by a waste-gate, an intake throttle and a downstream-compressor heat exchanger.

The engine model was developed using the ModEngine library [18]. ModEngine is a Modelica [19] library that allows the modeling of a complete engine with diesel and gasoline combustion models. Requirements for the ModEngine library were derived from the existing IFP-Engine AMESim<sup>1</sup> library. ModEngine contains more than 250 sub-models. It has been developed to allow the simulation of a complete virtual engine using a time-scale related to fractions of the crankshaft angle. A variety of elements are available to build representative models for engine components, such as turbocharger, wastegate, gasoline or Diesel injectors, valve, air path, EGR loop etc. ModEngine is currently functional in the Dymola tool<sup>2</sup>.

The engine model and the split parts were imported into xMOD model integration and virtual experimen-

<sup>1</sup>[www.lmsintl.com/imagine-amesim-1-d-multi-domain-system-simulation](http://www.lmsintl.com/imagine-amesim-1-d-multi-domain-system-simulation)

<sup>2</sup>[www.3ds.com/products/catia/portfolio/dymola](http://www.3ds.com/products/catia/portfolio/dymola)

tation tool [20], using the FMI export features of Dymola. The engine model has 118 state variables and 312 event indicators (of discontinuities).

## 5.2 Decomposition approach

The partitioning of the engine model is performed by separating the four-cylinder from the air path (AP), then by isolating the cylinders ( $C_i$ , for  $i \in [1, 2, 3, 4]$ ) from each other. This kind of splitting allows for the reduction of the number of events acting on each subsystem. In fact, the combustion phase raises most of the events, which are located in the firing cylinder. The solver can process them locally during the combustion cycle of the isolated cylinder, and then enlarge its integration time-step until the next cycle.

From a thermodynamic point of view, the cylinders are loosely coupled, but a mutual data exchange does still exist between them and the air path. The model is split into 5 components and governed by a basic controller denoted CTRL. It gathers 91 inputs and 98 outputs.

## 6 Tests and results

Tests are performed on a platform with 16GB RAM and 2 “Intel Xeon” processors, each running 8 cores at 3.1 GHz.

### 6.1 Reference simulations

The model validation is based on the observation of some quantities of interest as the intake and exhaust manifold pressures, air-fuel equivalence ratio and torque. These outputs are computed using LSODAR which is a variable time-step solver with a root-finding capability to detect the events occurring during the simulation. It has also the ability to adapt the integration method depending on the observed system stiffness.

The simulation reference  $Y_{\text{ref}}$  is built from the integration of the entire engine model, the solver tolerance (tol) being decreased until reaching stable results, which is reached for  $\text{tol} = 10^{-7}$  (at the cost of an unacceptable slow simulation speed).

Then, to explore the trade-offs between the simulation speed and precision, simulations are run with increasing values of the solver tolerance until reaching a desired relative integration error  $Er$ , defined by (6)

$$Er(\%) = \frac{100}{N} \cdot \sum_{i=0}^{N-1} \left( \left| \frac{Y_{\text{ref}}(i) - Y(i)}{Y_{\text{ref}}(i)} \right| \right) \quad (6)$$

with  $N$  the number of saved points during 1 s of simulation. Iterative runs showed that the relative error converge to a desired error ( $Er \leq 1\%$ ) for  $\text{tol} = 10^{-4}$ . The single thread simulation of the whole engine with LSODAR and  $\text{tol} = 10^{-4}$  provides the simulation execution time reference, to which the parallel versions are compared. When using the split model, each of its 5 components is assigned to a dedicated core and integrated by LSODAR with  $\text{tol} = 10^{-4}$ .

### 6.2 Effect of the context-based extrapolation on accuracy

To explore the effect of extrapolation on accuracy, the communication step has been set to  $250\mu\text{s}$  in a first set of experiments. This value has been chosen to provide acceptable results for the accuracy ( $Er \approx 1\%$ ), while being large enough to make extrapolation useful.

The tests show that performing only a fixed polynomial prediction (conventional first and second order extrapolation) on the engine model fails, with integration errors larger than for the reference simulation. This is due to the hybrid nature of the model, for which the extrapolation failures are caused by discontinuities, and also by sharp variations of some variables at specific instants. These cases totally waste the gain in precision due to successful extrapolation in the other parts of the state trajectories.

In contrast, using the context-based polynomial predictor, the outputs of the simulation are almost always closer to the reference trajectory than those computed when considering the inputs hold as constant (Figure 5).

Figure 5: Airpath output: pressure.

Figure 6 shows that using context-based extrapolation

tion, the prediction step is discarded when there is a discontinuous behavior in the signal, and that the degree of the predictor is adapted according to the signal slope (Figure 6).

Figure 6: Context behavior during simulation.

The cumulative relative integration error on a long simulation run is computed in Table 2. It shows that the context-based extrapolation efficiently decreases this error for the chosen variables, for example by 63 % for the temperature and by 72.5 % for the fuel density.

Table 2: Relative integration error.

Outputs	Er(%) w/o extrapolation	Er(%) w/ extrapolation
Pressure	0.499	0.304
Temperature	0.511	0.19
Air density	0.784	0.31
Fuel density	3.55	0.978
Burned gas density	4.99	3.47

### 6.3 Effect of the context-based extrapolation on simulation time

The ultimate objective of extrapolation is to decrease the simulation by stretching out the synchronization interval, while keeping the relative integration error  $Er$  inside predefined bounds. Indeed, widening the communication step from  $100\mu s$  to  $250\mu s$  without extrapolation (Figure 7) saves time but increases the error (e.g. 6.97 % for the burned gas density and 340.5 % for the fuel density).

Using the extrapolation for the  $250\mu s$  step fortunately decreases the relative error to values close to, or

below, those measured for the  $100\mu s$  step with frozen inputs.

Figure 7: Cumulative relative error using different communication steps.

Table 3 shows the simulation speed-up compared with the single-threaded reference. First note that when splitting the model into 5 threads integrated in parallel on 5 cores, the speed-up is supra-linear w.r.t. the number of cores. Indeed, the containment of events detection and handling inside small sub-systems allows for solvers accelerations, enough to over-compensate the multi-threading costs. Secondly, it appears that combining the enlarged communication step and the context-based extrapolation, the 10 % extra speed-up is reached without loss for the relative error. Even more surprising, using the extrapolation slightly speeds-up the simulation, possibly because the inputs shaped by the predictor enables a faster convergence of the solver step.

Table 3: Simulation speed-up.

Communication time	100µs	250µs	
Extrapolation	No	No	Yes
Speed-up	8.9	10.01	10.07

## 7 Conclusion and future work

The aim of this work is to speed up the numerical integration of hybrid dynamical systems, eventually until reaching a real-time execution, while keeping the integration errors inside controlled bounds. The basic approach consists in splitting the system into sub-models, which are integrated in parallel. Using large synchronization intervals between the branches allows for numerical integration speed-ups. However, slack

synchronization intervals may generate integration errors in the final result.

In this paper, the errors caused by the slack synchronization are modeled, giving directions to find effective trade-offs between integration speed and accuracy. Then, an approach of stretching out the communication steps while keeping a predefined integration precision is proposed. Rather than using costly small integration and communication steps, it uses extrapolations of the behavior of the models over the synchronization intervals. Test results on a hybrid dynamical engine model, show that well chosen context-based extrapolation allows for an effective speed-up of the simulation with negligible computing overheads.

This work shows that properly-chosen context-based extrapolation, combined with model splitting and parallel integration, can potentially improve the speed/precision trade-off needed to reach real-time simulation. However, the accuracy could be widely improved by accessing on the input derivatives of the models. This is the case for the FMI for co-simulation, and it would be highly useful to also integrate this feature in the FMI for model exchange. Future works intend to improve the context-based extrapolation algorithm, to make it more subtly aware of data freshness and even more decrease the prediction induced integration errors. Another possibility is to process the input signals to separate them into simpler components, easier to predict with different predictors, and to cope with noise. When it comes to polynomials, wavelet pre-processors [21] could be useful, as they play an important role in polynomial model fitting.

## Abstract

Virtual evaluation of complex Cyber-Physical Systems (CPS) [1] with a number of tightly integrated domains such as physical, mechanical, electrical, thermal, cyber, etc. demand the use of heterogeneous simulation environments. Our previous effort with C2 Wind Tunnel (C2WT) [2] [3] attempted to solve the challenges of evaluating these complex systems as-a-whole, by integrating multiple simulation platforms with varying semantics and integrating and managing different simulation models and their interactions. Recently, a great interest has developed to use Functional Mockup Interface (FMI) [4] for a variety of dynamics simulation packages, particularly in the automotive industry. Leveraging the C2WT effort on effective integration of different simulation engines with different Models of Computation (MoCs), we propose, in this paper, to use the proven methods of High-Level Architecture (HLA)-based model and system integration. We identify the challenges of integrating Functional Mockup Unit for Co-Simulation (FMU-CS) in general and via HLA [5] and present a novel model-based approach to rapidly synthesize an effective integration. The approach presented provides a unique opportunity to integrate readily available FMU-CS components with various specialized simulation packages to rapidly synthesize HLA-based integrated simulations for the overall composed Cyber-Physical Systems.

## 1 Introduction

Cyber-Physical Systems (CPS) [1] are composed of several collaborating physical and computing components that interact through embedded communication capabilities. These systems require advanced integration of abstractions and techniques that have been developed over the past years in disparate areas such as cyber systems that rely heavily on computation and networking and physical systems that employ various engineering methods in domains such as mechanical, thermal, electrical, electronic, hydraulic, thermal, biological, and acoustic.

Analysis of Cyber-Physical Systems poses unique challenges due to the heterogeneity of components and interactions [2]. The fundamental differences in the characteristics of these different physical and computation processes lead to a huge spectrum of modeling methods. For example, some components can be easily described by differential equations, while others like communication networks are better modeled as Discrete-Event Systems. As such, several simulation tools and techniques are needed for CPS simulation and analysis. This further necessitates an over-arching CPS model and system integration platform that is model-based and supports rapid synthesis of distributed heterogeneous CPS simulations.

Co-Simulation (Co-operative Simulation) is a simulation method that permits simulating individual components using different simulation tools simulta-

neously and collaboratively. Individual simulation tools exchange information such as system variables and their values, time steps for synchronization, and control signals for orchestrating the co-operative simulation. Thus, engineers can use different simulation tools together to create virtual prototypes of entire Cyber-Physical Systems. In practice, however, significant challenges remain with regard to the syntax and semantics of model and system integration.

In the Co-Simulation domain, a recent effort by the MODELISAR ITEA2 project that develops a tool independent standard called the Functional Mock-up Interface (FMI) [4] [7] [8] has gained significant influence, more prominently in the automotive industry. The FMI standard provides a well-defined specification and API to integrate simulation components. FMI-compliant simulations pack shared libraries that can be executed using the standardized function calls and the model execution must adhere to the rules of the standard. These function calls span all stages of the model execution, viz. initialization, configuration, access, modification, and manipulation.

The strength of FMI lies in the fact that all simulation tools participating in the Co-Simulation follow the defined standard and as such provides for standardized access to model equations. This permits coupling of Continuous-Time, Discrete-Time, and Discrete-Event that are part of a Cyber-Physical System. In some ways, this is also a limitation because not all simulation tools are amenable to support all of the strictly specified FMI function calls.

Another key requirement for Co-Simulation via FMI is to also develop a Master Algorithm (MA) that orchestrates the steps of Co-Simulation. Master algorithms have two tasks: (1) control the data exchange and (2) control time advancement among individual simulations according to the requirements of the integrated simulation of the overall Cyber-Physical System. Since the FMI standard does not describe or limit the implementation of the MAs, it basically leaves out the two fundamental challenges that all distributed simulation architectures face: *data exchange* and *time management*<sup>1</sup>. Solution for integrated data and time management in distributed simulations is technically complex and errors can easily lead to performance bottleneck and failures. This complexity pushes designers to adhere to the simplest solutions – losing much of the potential advantages of co-simulation.

<sup>1</sup> Theoretically, an MA for direct co-ordination among FMUs can be developed for each distributed simulation problem, but that would be expensive and subject to errors.

For example, Cyber-Physical Systems frequently involve vastly different sub-domains and physical processes that vary greatly in the execution frequency at which they need to run. This leads to significantly different dynamic response characteristics. For example, mechanical components of a complex CPS often have much slower frequency responses compared to fast electronic components. A single standalone monolithic model of a CPS therefore suffers heavily with solver inefficiencies. These systems are generally highly complex and have significant non-linearities and discontinuities, which further increases difficulties of gaining convergent solutions. Taking subsystems apart and using different solvers and step-sizes offers a potential solution. However, multirate composition also introduces inefficiencies due to time management, composition restrictions, data exchange, and potential stability issues if the system is split at the wrong place.

Challenges of distributed simulation have a long research history with notable results and standards. One of the widely used solutions developed by the U.S. Modeling and Simulation Coordination Office (M&S CO) is the High Level Architecture (HLA) [5]. The HLA provides a specification of a common technical architecture for modeling and simulation with a primary goal to facilitate interoperability among simulations and to promote re-use of simulations and their components. The HLA comprises of three major components: HLA rules, HLA interface specification, and HLA object model template [5]. With these rules, the HLA standardizes run-time support for various tasks, such as coordinated time evolution, message passing and shared object management. The key difference between FMI and HLA is that HLA provides a standard for data exchange and time management for individual simulation processes. This enables broader integration of different simulation tools using different Models of Computation. Functional Mock-up Units can be integrated as a participating simulation tool in the overall integrated simulation of the Cyber-Physical Systems.

A key benefit of HLA is that its Distributed Discrete Event model of computation allows full flexibility to individual subsystems in using any internal solver and model of computation. Moreover, this flexibility permits multirate simulations by design.

However, the HLA standard also lacks some key facilities for developing integrated distributed heterogeneous simulations. For example, the HLA standard does not formalize methods for developing interactions and objects used by HLA federates and it does not provide facilities for easily moving simulations from one computational node to other. Consequently, HLA-based simulations also require a sig-

nificant amount of tedious and error-prone hand-developed integration code.

Achieving the integrated simulation of Cyber-Physical Systems require effective integration of a huge spectrum of models of physical processes, communication systems, exchanged information, and control mechanisms. As detailed above, the approaches of FMI and HLA both have their advantages and some key limitations. The approach of using HLA as a master algorithm enables use of FMUs in a Co-Simulation environment while also providing flexibility of using other types of non-FMU simulations [9]. The resulting framework can provide a much broader scale of simulation tools that can be used in the integrated simulation of Cyber-Physical Systems. However, several gaps need to be filled in order to develop a platform that enables this integration in an efficient manner. A single efficient model-based platform is needed that:

- Enables modeling of interactions and shared objects between simulation tools
- Enables modeling and integration of systems with their data exchange mechanisms
- Enables modeling of deployment of simulation tools on distributed computational infrastructure
- Provides a standard master algorithm for FMI Co-Simulation
- Enables multirate modeling with dynamic time management
- Provides a set of tools to generate necessary artifacts for rapid synthesis of simulations

This paper attempts to address these important challenges in creating a single coherent platform for developing integrated distributed simulations of Cyber-Physical Systems. We build upon our previous work on a model-based integration platform called the Command and Control Wind Tunnel (C2WT) [2] [3].

The rest of the paper is organized as follows. Section 2 and 3 give an overview of the C2 Wind Tunnel and FMI for Co-Simulation respectively. We present our detailed model-based integration approach in Section 4 and provide a detailed case study with experimental results in Section 5. Section 6 provides the related work and Section 7 concludes the paper.

## 2 C2 Wind Tunnel

Over the past several years, we have developed a model-based multi-model integration platform called the Command and Control Wind Tunnel (C2WT) [2] [3]. It is an integrated, graphical, multi-model, dis-

tributed simulation environment for the experimental evaluation of large-scale C2 systems with various organizational and technical architectures. It enables a variety of simulation engines to interact and transmit data from one another and log and analyze simulation results. Figure 1 below gives a conceptual architecture of C2WT.

The High-Level Architecture is a standardized framework for distributed computer simulation systems. Communications between different federates is managed via the Run-Time Infrastructure (RTI) layer. The RTI provides a set of services such as time management, data distribution, message passing, and ownership management. Other components of the HLA standard are the Object Model Template (OMT) and the Federate Interface Specification (FIS).

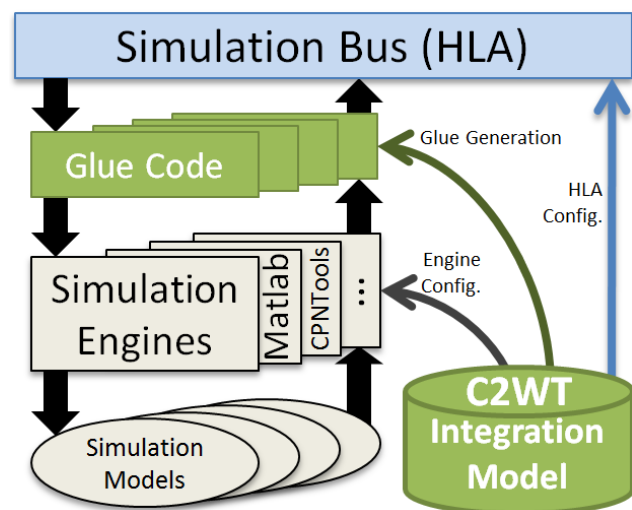

Figure 1: Conceptual architecture of C2WT

The HLA standard focuses on three primary areas. First is time coordination throughout the federation. The evolution of time is a key thread through each of the integrated simulators. Each simulation platform must slave its progression of time to that of the overall HLA clock. The HLA standard provides several methods by which to accomplish this. Second is coordination of inter-federate messages and shared data objects. The HLA standard provides a publish-and-subscribe mechanism for passing messages and object updates throughout the federation. Third, the HLA standard provides for basic simulation execution control. Starting, pausing, and stopping the execution of a simulation is built directly into the HLA standard. The C2 Wind Tunnel relies upon all of these services during run-time.

As HLA is an accepted standard, a number of commercial, academic, and alternate RTI implementations are available. Currently, we use the Portico

RTI [10] – which provides support for both C++ and Java clients and is compliant with version 1.3 of the HLA standard.

The HLA provides a standard for the RTI that supports the coordinated execution of distributed simulations. However, designing the model integration, coding the platform-to-RTI glue-code, and testing and deploying all of the various run-time components across multiple platform-specific simulation tools is a highly challenging task. C2WT provides a solution to this simulation integration problem. It provides a holistic modeling and management environment built around a custom Domain-Specific Modeling Language (DSML) [11], implemented in Generic Modeling Environment (GME) [11], and a related suite of model interpreters to coordinate between the integration model and the platform-specific simulation tools involved in the overall environment. It facilitates the rapid development of integration models and use of these models throughout the lifecycle of the simulated environment. With simulation engine specific model configurations and experiment specific deployment modeling, it enables significant automation in the development of integrated distributed simulation. With integration modeling support and various sophisticated generation tools, C2WT provides a robust platform for users to rapidly model and synthesize complex, heterogeneous, command and control simulations.

### 3 FMI for Co-Simulation

Functional Mock-up Interface (FMI) [4] [7] [8] was initiated and organized by Daimler AG within the ITEA2 project MODELISAR [4]. The FMI standard consists of two main parts. The first part is FMI for Model Exchange, which standardizes the distribution of a dynamic system model in the form of generated C-Code as an input/output block to other simulation environments. The second part is FMI for Co-Simulation, which standardizes the mechanisms for coupling of two or more simulation tools in a co-simulation environment.

The key idea is to have a discrete set of communication points only, at which times the subsystems exchange any data. Outside of these points, the subsystems are executed independently. The data exchange is controlled by a master system that also manages time synchronization of subsystems.

The FMI Co-simulation master simulator couples the subsystem simulators through a zip-archive. This zip-archive contains shared library files (.DLL, .SO) that conform to the function call specifications given in the standard. Each zip-archive also contains a

XML file that provides meta-data and further details of the model such as default start and stop times, variable types, units, tool specific data, parameter and variable names and attributes. The XML also contains specification for executing the model as a shared library during a simulation run (CoSimulation\_Standalone) or by importing a slave tool wrapper and interfacing it with the external tool (CoSimulation\_Tool).

## 4 Model-Based Integration

One of the primary contributions of our effort is our focus on developing a completely model-based integration approach. Our efforts leverage the Generic Modeling Environment (GME) [11] tool suite for designing the integration model DSML [11] and HLA [5] to provide run-time support as the “simulation bus”.

### 4.1 Needs and Challenges

Cyber-Physical Systems [1] [2] are highly complex and their simulation spans a multitude of computational domains and specializations. A large number of tools exist that have been developed for specific aspects of CPSs. A variety of tools exist even for a single aspect of CPSs. For example, many special purpose simulation tools exist to model and analyze vehicle dynamics or for switching mechanisms of hybrid drivetrains. As such the integration platform must be open toward use of any tool that may be required for some component/aspect of the CPS simulation.

A subtle problem in using multiple simulation tools in an integrated simulation is that they tend to use many different Models of Computation (MoC). For example, Discrete-Event, Discrete-Time, Continuous-Time, Synchronous Dataflow, are among the many MoCs used. Each MoC has a specific mechanism for time progression and event handling. The integration platform must be able to handle tools that use different MoCs in highly flexible manner. The integrated system must respect time synchronization with other simulation tools as well as the causality of events must be preserved. In addition to system integration, the platform must also enable integration of models by means of capturing the communication (with any translation that might be needed) that occurs between them.

In general, it is preferable to have a graphical environment that provides well-defined semantics for modeling concepts, their relations, and rules for composition. Moreover, for rapid synthesis of simu-

lations, the platform must support tools for translation of models to executable software that conform to specified executable semantics. The automation not only provides efficient development of simulations, it also significantly minimizes human errors.

The integration environment should also provide capabilities for modeling and configuration experimentation and logging.

Furthermore, when FMUs are integrated the rules of FMI must still be adhered to. Particularly, the models in the FMUs must be accessed, controlled, and manipulated using the function calls specified in the FMI standard.

## 4.2 Meta-modeling

The Generic Modeling Environment is a meta-programmable model-integrated computing (MIC) [11] toolkit that supports the creation of rich domain-specific modeling and program synthesis environments. Configuration is accomplished through meta models, expressed as UML class diagrams, specifying the modeling paradigm of the application domain. Meta models characterize the abstract syntax of the domain-specific modeling language, defining which objects (i.e. boxes, connections, and attributes) are permissible in the language. Another way to envision this is that a DSML [11] is a schema or data model for all the possible models that can be expressed by a language. Using finite state machines as an example, the DSML would consist of states and transitions. From these elements any state machine can be realized. The inherent flexibility and extensibility of the GME [11] via meta models make it an ideal foundation for the C2 Wind Tunnel environment. Alternate meta modeling frameworks have also been developed in the past, such as AToM3 [12], MetaCase [13], Microsoft DSL [14], and the Eclipse Modeling Framework [15].

## 4.3 Model-Based Integration of FMUs in C2WT

As detailed in section 2, C2WT provides an overarching modeling and management environment and a suite of model interpreters to coordinate the integration models and platform-specific simulation tools involved in the overall heterogeneous distributed simulations. The user is referred to [2] for details of the meta-modeling language and its executable semantics. In this section, we further discuss the integration of FMUs as HLA-federates in the C2WT platform.

In this work, the C2WT metamodel was further customized to enable FMU specific federate specifi-

cations. Although the original C2WT metamodel is sufficient to support integration of newer types of federates, having simulation tool/technique specific first-class objects in the modeling language makes reasoning about such entities more flexible and can support extensive automation. The FMU-federate model specifies the location of the zip archive, whether to log variable values during simulation, additional variables (other than input and output) to log, and ratio of macro and micro steps for multirate simulations.

Figure 2 below shows the extension to the original C2WT architecture to incorporate FMU federates in the platform.

Figure 2: C2WT extended for FMI-CS

Our model interpreters can read the models with specified input and output relationships with other simulation tools and even other FMUs and can automatically generate all the executable code that can be deployed on different nodes in the available computational infrastructure for the simulation. As previously mentioned, C2WT supports simple modeling of computational infrastructure and assignment of federates on its nodes.

Following the rules of FMU access, modification, and manipulation as described in the FMI standard [4] [7], we developed a simplified procedure for FMU-federate execution as given below:

### Initialization phase (before simulation start):

- 1: Load FMU zip archive, read model description
- 2: Load shared libraries in the FMU
- 3: Instantiate the FMU slave
- 4: Setup input/output and HLA-interaction maps
- 5: Setup up logging

### **Execution phase (during simulation):**

- 1: Synchronize start of simulation with all tools
- 2: Request RTI to proceed to step-size and wait
- 3: Update input variables with HLA updates
- 4: Call *doStep* in step-size/#micro-steps chunks
- 5: Continue #4 until full step-size is executed<sup>2</sup>.
- 6: Update HLA with output variables
- 7: Go to #2

Please note that above is rather simplified procedure of FMU integration mechanism in C2WT. The actual implementation also involves setting up statistical and database logging, micro-step management to avoid overlaps, error-handling, efficient federate code execution, reliable & reusable time advancing facilities, and model state and HLA interaction synchronization.

## **5 Case Study**

To illustrate our model-based approach for FMU integration in C2WT we present a high-fidelity model of a representation of a Vehicle Thermal Management (VTM) system which is intended for studying interactions of thermal management systems within a vehicle.

### **5.1 Model description**

This particular example is a conventional four wheel chassis and drivetrain architecture with a spark ignition engine and standard transmission. These mechanical systems are created using components from the Vehicle Dynamics Library (VDL) from Modelon [16]. The model also includes a representation of the coolant loop for the engine and transmission oil loop in conjunction with a four heat exchanger stack for the thermal domain. These portions of the model are constructed from components of the Liquid Cooling Library (LCL) from Modelon. A snapshot of the overall model is shown in the following Figure 3 below.

The key component models of the system are: Driver, Vehicle (Engine, Transmission, Driveline, Chassis, Aerodynamics, External loads, and Brakes), Lumped engine thermal mass, Lumped transmission thermal mass, Engine coolant fluid circuit, Transmis-

sion oil cooling circuit, Heat exchanger stack, Low voltage battery, Alternator, Cooling fan and controller, and Grill shutters and controller. Table 1 below provides key features of these component models.

Since the purpose of this model is to study vehicle thermal dynamics, a simplified 1D longitudinal dynamics chassis model is used rather than a full 3D body model. This allows for faster simulations of the typically long duration drive cycles.

*Table 1: Key features of component models*

<sup>2</sup> Note that an FMU freely updates its internal variables during micro-steps, but the input variables at the beginning of step #4, remain unchanged during step #5. Each subsequent micro-step, within the step #5, uses the updated internal variables in previous micro-step. Also, it is assumed that FMUs do not reject time-steps.

During the simulation, heat that is generated by the engine is stored within the engine thermal mass and then rejected to the coolant-to-air heat exchanger (radiator) through a coolant fluid loop. A similar loop and heat exchanger also exists for the transmission.

The model is well suited to thermal management controller design, studying tradeoffs between thermal management energy demands and fuel economy, heat exchanger efficiency and sizing, and coolant fluid flow dynamics.

For this paper, the model was partitioned into separate executables by dividing the model along domain boundaries. In this case the vehicle mechanics, electrical, and driver were grouped into one model while the fluid and thermal portions of the model were grouped into another. This partitioning allows for execution of Driver vehicle and Thermal management parts at different rates. Owing to the inclusion of fluid portions in the Thermal management part, this part needed to run with a much lower step-size than the Driver vehicle part to maintain system stability.

In order to do this the physical connections that are bisected by the boundaries must be converted to causal signals. As an example for the engine, the heat is generated within the mechanical portion of the model. The heat is directed to the lumped thermal model, within the thermal portion of the model, which determines the thermal mass temperature. Images of these two systems are shown in Figures 4 and 5 below.

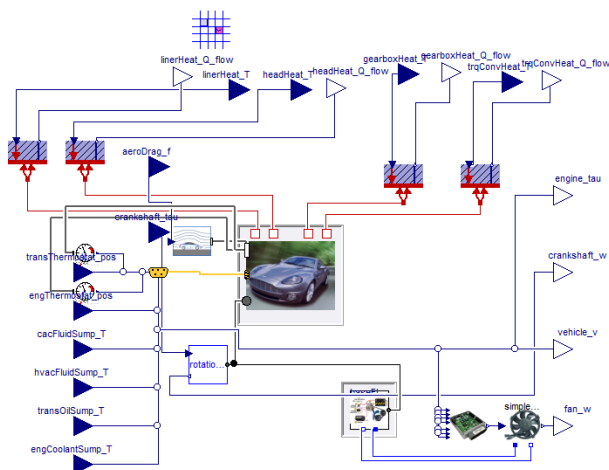

Figure 4: Driver vehicle model

Figure 5: Thermal management model

## 5.2 Simulation architecture

The simulation setup consisted of mainly three federates, viz. Driver vehicle, Thermal management, and the Manager federate. Manager federate is an auto-generated external federate, which is used mainly as a front-end controller of the overall heterogeneous simulation. The simulation architecture is illustrated in the Figure 6 below.

Figure 6: Simulation architecture

## 5.3 Data and Integration model

The actual data and integration model are given in the Figures 7 and 8 below. These show the input and variables from the Driver vehicle and Thermal management federates. These two models are executed as FMUs in the C2WT.

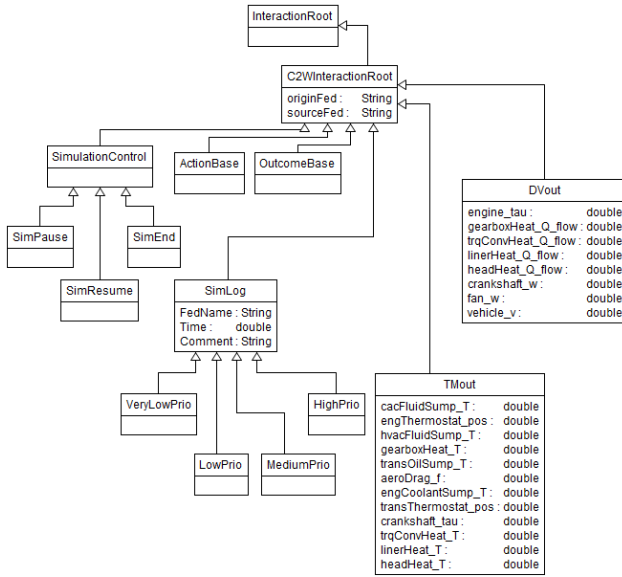

Figure 7: Data model

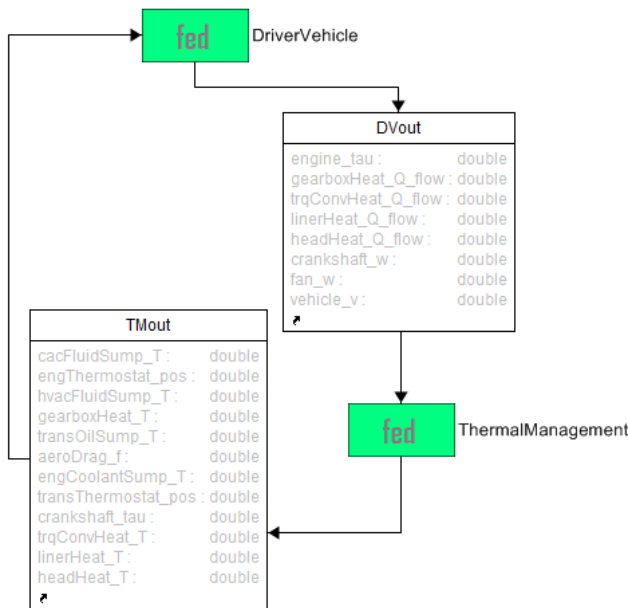

Figure 8: Integration model

## 5.4 Experimental Results

For the experiment, the Driver vehicle and Thermal management FMUs were exported from Dymola [16] models by Modelon, Inc. [16]. We used a JFMI Ptolemy APIs [17] to connect the FMUs to our Java based C2WT platform. All federates were running in a single Ubuntu 32 virtual machine. The Run-Time Infrastructure (RTI) used was Portico [10]. Total simulation time for the experiment was 50 seconds.

The simulation was setup as a multirate simulation with different step-sizes for the three federates: Driver vehicle (10 ms), Thermal management (5 ms), and Federation Manager (100 ms). The entire simulation ran in about ~9 minutes. The Figures 9 and 10 above show the experimental results for the total 50 seconds of simulation time. It should be noted though that the VTM models used were currently not optimized for efficiency.

From the experimental results, we found closely matching plots with same peak and trough values that were in the equivalent single monolithic (combined Driver vehicle and Thermal management) model. The overall runtime (~9 minutes) was also comparable to standalone single model simulation time in Dymola (~6 minutes) despite the use of a third federate (viz. Manager federate) in the simulation and delays due to inter-process communications.

The models were developed with a variable step solver as requirement. However, they could still run with a fixed step solver (with a maximum step-size of 1.5 ms). However, with our setup of separating the Driver vehicle and Thermal management components as separate FMUs and executing them through C2WT platform, we could even execute these components at 10 ms and 5 ms step-sizes respectively.

Figure 9: Vehicle speed and crankshaft angular velocity

**ideal1DSedanCycleFollower.driver.gearRobot.gearSelection**

*Figure 10: Gear selection and Liner heat flux*

Yet another experiment we have performed is the one where we placed a network simulator for the CAN bus that must be placed between the above two components. We used the OMNeT++ simulator [18] to model that. In this experiment, we varied the rates of the FMUs to initially match the rate at which network simulator was run, viz. 0.5 ms, and then in the second setup we increased the step-size of Driver vehicle and Thermal management to 1 ms. We found that the results still matched while in the second setup they executed in about one-third the overall wall-clock time. We omit further details of experiment setup here for brevity. In the future, we plan to further publish our work focusing specifically on the multirate aspects in distributed CPS simulations.

## 6 Related Work

Distributed simulation of Cyber-Physical Systems [1] is a highly challenging endeavor with its unique set of requirements. In the past a number of researchers have attempted to solve these problems.

Some approaches aim at providing an integration mechanism for two or three tools used in CPS simulation. For example, [20] shows integrated CPS simulation by coupling Matlab and a network simulation called EPANET, [21] presents an integration approach using SysML and numerical solvers, and [22]

presents a co-simulation platform using Modelica framework and the ns-2 network simulator. There are also approaches to provide a complete dedicated simulation environment. For example, [23] [24] presented a unified software environment for model-based integration and multi-granular evaluation of widely used simulators. A simple master algorithm for Co-Simulation using FMI was given in [25] and a framework providing a central master simulator for FMUs as well as live components was provided in [26]. A dedicated environment for modeling with different models of computations and their execution via HLA was presented in [27]. Also, a co-simulation tool-chain has been proposed in [28], where existing system components from domains such as TinyOS and Modelica can be imported into SysML and then converted into corresponding FMU blocks. It was recently argued in [29] that it may be feasible to create a HLA-based master algorithm for FMI Co-simulations and then later a method was proposed in [9] [30] [31].

Our work focusses on providing a framework to enable model-based rapid synthesis on CPS simulations. The origins of our model-based approach can be found in [32]. Further, [33] explains how model-based rapid synthesis can lead to development of Cyber-Physical Systems with continuous integration techniques. The C2WT framework [2] developed at our institute facilitates model-based rapid integration of heterogeneous and distributed simulations. Recently, C2WT framework was used to develop an evaluation tool for networked control systems in [34].

## 7 Conclusions

In this paper, we have successfully demonstrated a model-based integration approach to rapidly synthesize multi-model distributed simulation that may also involve co-simulation FMUs as component models. The FMUs are automatically wrapped as HLA-federates that can be executed in the C2WT platform.

We also illustrated that different federates can be run with different clocks and their synchronization in C2WT is managed using HLA time management facilities. We have also integrated FMU-CS in simulations that also use other simulation tools such as a network simulator or a 3D terrain simulator. The integration of other federates in C2WT has been previously demonstrated in [2]. Thus C2WT provides a broader range of simulation tool integration that involves FMI and non-FMI simulations to enable development of System-of-System (SOS) simulations.

C2WT supports real-time and as-fast-as-possible modes of simulation execution. However, currently the real-time simulation requires that the individual component simulations can run faster than real-time.

C2WT also supports human-in-the-loop simulations with real-time simulations. In this case human interaction with running simulations (e.g. in military training exercises) is performed using HLA-interaction mappings.

One of the key benefits of C2WT platform is its support for extensive experimentation, message logging, state variables logging, and analysis support.

The research at our institute is currently ongoing with the applications of FMI Co-Simulation using HLA-based integrations. We anticipate novel methods for FMI Co-Simulations that are rapidly synthesized and may perform faster than single monolithic simulations.

We are also working on extending the C2WT platform to support other simulation techniques and tools such as SystemC.

## Abstract

Conceptual design of systems requires aggregate level simulations of the designed system in its operational setting. By this way, performance of the system and its interactions with the other entities in its environment can be evaluated. The complex nature of these simulations often requires distributed execution. IEEE 1516 High Level Architecture (HLA) is a widely accepted standard architecture for distributed aggregate level simulations. Functional Mock-up Interface (FMI) is a recent standardization effort that leads to a tool independent systems simulation interface that enables model reuse and co-simulation. This paper aims to present a method for developing HLA-compliant federates using FMI. The method enables a Functional Mock-up Unit to join an HLA-compliant federation as a member.

*Keywords: Functional Mockup Interface; High Level Architecture; Distributed Simulation*

## 1 Introduction

Systems development process starts with conceptual design phase in which designers create concepts and conduct trade off analysis. Modeling and simulation have always been essential tools for conceptual design. Early stage systems modeling aims to identify the system requirements and its interactions with its operating environment. Effect based models, integrated in a large scale operational settings are used to evaluate the performance of the system concerning the accomplishment of its mission. Simulation of the mission space of a system requires modeling large

number of entities and often simulating them in a distributed fashion. IEEE 1516 High Level Architecture (HLA) standard [1] [2] [3] is commonly used to integrate loosely coupled models of the entities in a mission space.

The Functional Mock-up Interface (FMI) is a newly developed, tool-independent model interface standard [4] [5]. Its main purpose is to model reuse between various modeling tools and environments throughout the systems development phases. A simulation component conforming to FMI is called a Functional Mock-up Unit (FMU), whose contents include a model description file, user defined libraries, source codes, model icons and documentation.

FMI and HLA has completely different behavior. While HLA supports to work at process level, the master of the FMU does not care about the topics such as entity transfer, shared resource management, time synchronization or ownership management [10].

On the other hand, there is a potential to reuse existing FMUs as federates in an HLA-compliant distributed simulation, i.e. federation. By this way, FMI will also serve as a model interface for distributed simulation entities in the concept of design phase. Here in this study, we introduce a mechanism to develop Functional Mockup Unit Federates (FMUFd) from FMUs.

### 1.1 Related Work

As model based development of engineering systems are getting more popular, connecting engineering models to the distributed simulation environments is also becoming an important issue of concern [6][7]. There have been some attempts for developing such tools and methodologies. Closely related to our work,

there exist two particular efforts providing a mechanism for connecting models to HLA environments.

MatlabHLA-Toolbox [8] and HLA Blockset [9] are available toolboxes to provide HLA communication feature to the Matlab. With these toolboxes, modelers can create a federate, join a federation and start publishing and subscribing entities and events. However, these solutions can only work in Matlab environment.

In [10], authors introduce an approach to run FMI Co-Simulation environment over HLA. They employ HLA RTI as a master to synchronize the simulation that is composed entirely of FMUs. They define an Object Class derived from the interface specifications of all participating federates and let each federate out of an FMU publish or subscribe its required attributes. In contrast, our approach enables participation of FMUs in a federation with non-FMU members as well.

## 2 Functional Mockup Interface

Functional Mockup Interface provides an interface specification for simulation components called Functional Mockup Units. FMI provides two standard interfaces, namely, FMI for Co-Simulation and FMI for Model Exchange [4] [5].

While FMI for Model Exchange specifies the interface for callers with explicit or implicit integrators, FMI for Co-Simulation specifies the interface for simulation runnables that possess solvers in them. As we can view HLA Federates as standalone simulation runnables, this effort is based on FMI-Co-Simulation interface for federate development. In this work, the first version of the standard is used as the baseline [5].

### 2.1 FMI for Co-simulation

As mentioned above, FMI for Co-Simulation is a standard interface for the model output containing its solver inside. Therefore, the user does not need to know which integration method is actually employed to solve the ordinary differential equations within the model.

For each of the FMU in a co-simulation environment, the communication capabilities are configured in a model specific XML file, namely *ModelDescription.xml* file. Communication with an FMU can only be realized in a discrete communication point, which is a sampling point or a synchronization point of the FMU [5].

#### 2.1.1 Computational Flow

As show in Figure 1, FMU co-simulation computational flow has three main states, namely Instantiation and Initialization, Running and Termination.

##### Instantiation and Initialization

A new FMU instance is created and initiated to be ready to run. Memory allocations and initial value setting for the FMU parameters are performed in this phase.

##### Running

In this phase, FMU model is executed via calling *doStep()* method. Intuitively, before running a step, FMU input parameters are set by calling *fmiSetXXX(...)* and after the completion of this step the model output parameter are read by the master via calling *fmiGetXXX(...)*.

##### Termination

The model component is unloaded and the memory is cleaned up in this phase.

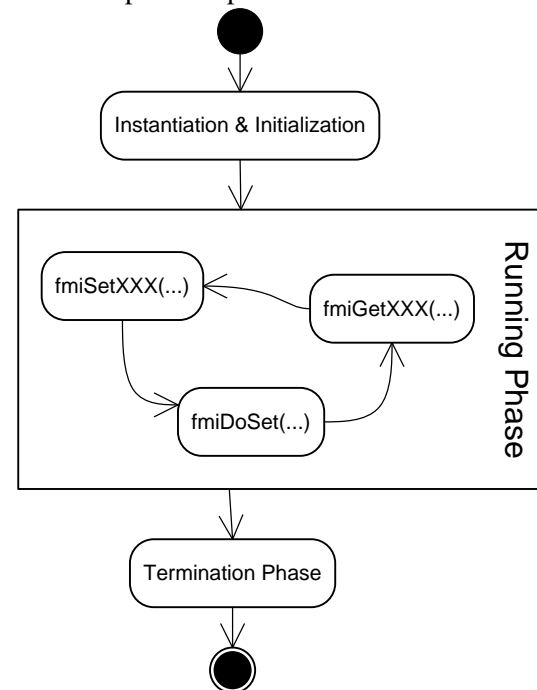

Figure 1 – FMU Co-Simulation Model Computational Flow

## 3 High Level Architecture

The High Level Architecture (HLA) is a common framework for distributed simulation systems. HLA promotes interoperability between heterogeneous simulations and supports the reuse of models in different contexts. HLA provides communicating data and synchronization actions between simulation members regardless of their computing platforms [1].

HLA combines simulations (federates) into a larger simulation (federation), where federates are

components and federations are component based applications. The HLA requires runtime infrastructure (RTI) software to support the operation of a federation execution. RTI provides a set of services and by using these services a federate can interact with the federation at runtime. How a federate can utilize these services is defined by the Federate Interface Specification [2].

Federation Object Model (FOM) is the HLA Federation Object Model that describes all of the object classes and interactions, attributes of object classes and parameters of interactions for the federation. Also, FOM establishes the information model contract which governs the simulation. Simulation Object Model (SOM), on the other hand, is the HLA Simulation Object Model that describes the object classes and interactions, attributes of object classes and parameters of interactions information which are exposed or consumed by a federate [2].

### 3.1 HLA Services

HLA provides six groups of services to enable distributed simulation in an aggregate level [2]. Federation Management describes how to create, join, resign and manage federations, save and restore federation states. Declaration Management defines the publishing and subscribing to objects and attributes. Object Management service states how to register new instance of an object class or interaction, update the attributes, receive interactions, discover new instances and receive updates of attributes. Ownership Management defines acquisition of ownership of the registered objects. Time management describes how a federate can advance its logical time along with other federates and how to deliver the time-stamped events ensuring that a federate can never receive an event with a timestamp less than the federate's logical time. Data distribution management defines the production and consumption of data to bind the relevance of communication data among federates. As a result, RTI can recognize the irrelevant data and prevents its delivery to consumers.

### 3.2 HLA Object Model

HLA provides object classes and interactions as the object models, which are used to publish/subscribe the data over distributed simulation environment. Providing the data exchange between federates is one of the responsibilities of the RTI.

An **object class** can be derived from another object class. *HLAObjectRoot* is the base class of the all object classes. Each object class can contain one or more at-

tributes. Derived classes also inherit base class attributes. Attributes have data types. A federate will publish/subscribe only interested attributes of an object class; it does not have to deal with all the attributes in an object class.

An **interaction** can be derived from another interaction. *HLAInteractionRoot* is the base class of the all interactions. Each interaction contains one or many object parameters. Derived interactions takes base interaction parameters also. Parameters have data types. A federate should fill all the parameters of an interaction to publish it.

HLA provides six different **data types** where user can create variety of data structures by using those data types. The published/subscribed values are stored in these data structures. The details of data types are given below [3]:

- **Basic Datatype:** Basic data refers to a predefined set of data representations. Following data types should be defined by any OMT: *HLAinteger16BE*, *HLAinteger32BE*, *HLAinteger64BE*, *HLAfloat32BE*, *HLAfloat64BE*, *HLAoctetPairBE*, *HLAinteger16LE*, *HLAinteger32LE*, *HLAinteger64LE*, *HLAfloat32LE*, *HLAfloat64LE*, *HLAoctetPairLE*, and *HLAoctet*.
- **Simple Datatype:** The simple data type table refers to simple, scalar data items. Following data types should be defined by any OMT: *HLAASCIIchar*, *HLAunicodeChar*, and *HLAbyte*.
- **Enumerated Datatype:** The enumerated data type refers to data elements that can take on a finite discrete set of possible values. Following data type should be defined by any OMT: *HLAboolean*.
- **Array Datatype:** The array data type table refers to indexed homogenous collections of data types; these constructs are also known as arrays or sequences. Following data types should be defined by any OMT: *HLAASCIIstring*, *HLAunicodeString*, and *HLAopaqueData*.
- **Fixed Record Datatype:** The fixed record data type table refers to heterogeneous collections of types; these constructs are also known as records or structures. This allows users to build structures of data according to the needs of their federate or federation.
- **Variant Record Datatype:** The variant record data type table refers to discriminated unions of types; these constructs are also known as variant or choice records.

### 3.3 HLA Padding Rules

HLA requires that certain types of data start at a particular kind of location. Therefore, usually there is a requirement for extra bytes, namely padding bytes,

between data fields in a structure. To illustrate, consider a structure where the first field is a byte and second field is a double. Double must start at a position which is a multiple of 8. Therefore, seven bytes of padding is needed between byte field and double field for a proper structure.

The padding rules are used to determine exact positions of the fields of a data type, which constructs the data structure of an attribute.

These rules for constructed data types (arrays, fixed records, and variant records) as described below [3]:

#### Base Datatype

Each base type has a boundary value as provided in table 1. During the calculation of padding, this table is used to calculate structure boundary value.

Table 1 – Basic Datatype Boundary Values

Basic representation	Octet Boundary Value
<i>HLAoctet</i>	1
<i>HLAoctetPairBE</i>	2
<i>HLAinteger16BE</i>	2
<i>HLAinteger32BE</i>	4
<i>HLAinteger64BE</i>	8
<i>HLAfloat32BE</i>	4
<i>HLAfloat64BE</i>	8
<i>HLAoctetPairLE</i>	2
<i>HLAinteger16LE</i>	2
<i>HLAinteger32LE</i>	4
<i>HLAinteger64LE</i>	8
<i>HLAfloat32LE</i>	4
<i>HLAfloat64LE</i>	8

#### Simple Datatype

Same base data type padding rules also apply for simple datatype.

#### Enumerated Datatype

Same base data type padding rules also apply for enumerated datatype.

#### Fixed Record Datatype

The padding bytes are added to each field when necessary to ensure that the next field in the record is properly aligned. After a field the padding bytes can be calculated by using the following formula:

$$(Offset_i + Size_i + P_i) \bmod V_{i+1} = 0$$

where  $Offset_i$  refers to the offset of the  $i$ 'th field of the record as bytes,

$Size_i$  refers to the size of the  $i$ 'th field of the record as bytes,

$V_{i+1}$  is the octet boundary value of field  $(i + 1)$ th of the record.

#### Variant Record Datatype

The *HLAvariantRecord* encoding shall consist of the discriminant followed by a field. This field is chosen by using the value of discriminant. The discriminant is placed at offset 0 of the record. The padding bytes  $P$  are calculated by using the following formula:

$$(Size + P) \bmod V = 0$$

where  $Size$  refers to the size of the discriminant as bytes, and  $V$  refers to the maximum of the octet boundary values of the alternatives.

#### HLA Array Datatype with Fixed Cardinality

The padding bytes  $P_i$  between  $i$ 'th and  $(i+1)$ th elements can be calculated by using following formula:

$$(Size_i + P_i) \bmod V = 0$$

where  $Size_i$  is the size of the  $i$ 'th element of the array in bytes,

$V$  is the octet boundary value of the element type.

#### HLA Array Datatype with Variant Cardinality

The first 4 bytes are used to present the number of the elements in the array. These 4 bytes are encoded as *HLAinteger32BE*. The padding bytes can be added between the inform element and the first element of the sequence. The padding bytes can be found by using following formula:

$$(4 + P) \bmod V = 0$$

where  $V$  is the octet boundary value of the element type.

## 4 Functional Mockup Unit Federate Design

The FMI for Co-Simulation standard does not provide a specification for connecting FMUs to an HLA federation, hence, FMI Co-Simulation does not have an interface ready to utilize HLA services. Moreover, there is no convenient way to convert FMU scalar variables to HLA object class attributes, because FMI Co-Simulation only supports the following primitive types: *real*, *integer*, *string*, *Boolean* and *Enumeration*. On the other hand, HLA attributes can represent any data type structure, from basic data types to the complex data type structures. Since FMI Co-Simulation scalar variables can only map to HLA basic data types, a simulation environment using complex data types cannot be directly supported by FMI Co-Simulation.

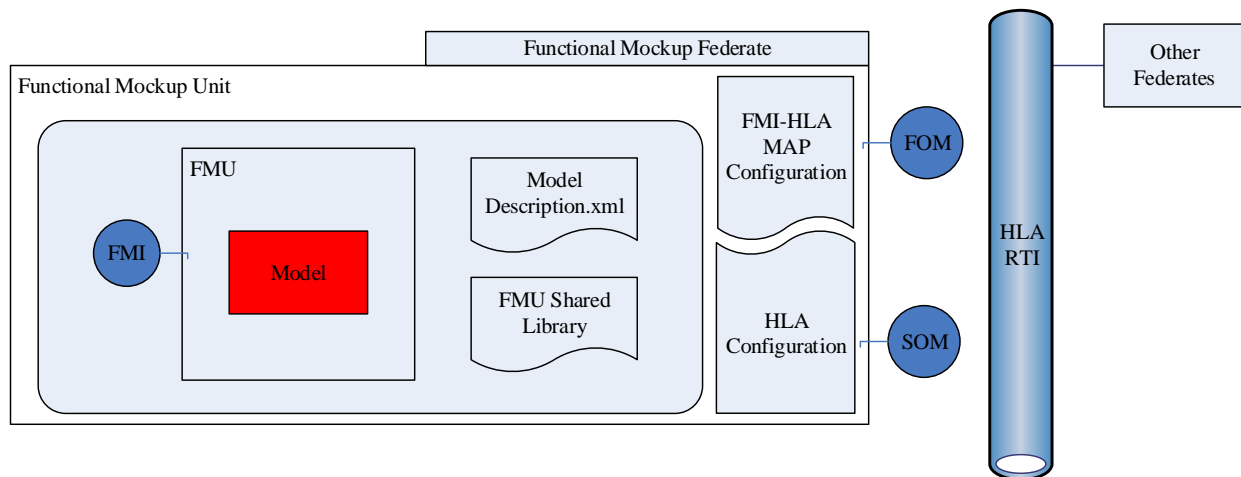

Figure 2 – Functional Mockup Unit Federate

Hence, there is a need for a wrapper that connects an FMU, in the context of FMI Co-Simulation, to the HLA distributed simulation environment. The work conducted handles the problem by designing a Functional Mockup Unit Federate (FMUFd). FMUFd has the following responsibilities:

- Instantiating, initializing, stepping and terminating of a FMU model.
- Providing the communication of distributed environment with services by using the HLA standard interface.
- Converting FMU model outputs to compatible HLA data types and sending them as HLA object updates.
- Receiving model inputs from HLA objects and converting them to compatible FMU types.

The top level structure of FMUFd that satisfies these requirements is depicted in Figure 2. The FMUFd is composed of the FMU model, FMI-HLA Map configurations and HLA connection configuration. FMI-HLA Map Configuration is used to inform FMUFd about HLA FMI relation. For each FMU, using this structure an FMUFd is needed to be configured. HLA connection configuration is related with the federation and FOM information of distributed simulation environment. By using these data, FMUFd runs with stepwise activities. As shown in Figure 3, these activities can be grouped into four main phases, namely, initialization, object discovery, stepping and termination.

In **initialization** phase, FMUFd loads and initializes the FMU and then connects the HLA federation as a federate with related HLA services and declare interested object classes for publishing and subscribing.

In **object reflection** phase, the subscribed object class instances are discovered and their values are reflected.

The **stepping** phase is the main phase of the simulation. In this phase, FMU input variables are reflected from related HLA objects, FMU runs one time step, and then, FMU output values are reflected to related HLA objects.

In **termination** phase, FMUFd terminates and unloads FMU, resigns from federation, frees allocated memory and finally stops.

The details of these steps with the process of connecting FMU to the HLA simulation environment will be described in the following sections. After that, the FMUFd capabilities in terms of the HLA services and FMUFd limitations will be mentioned briefly.

#### 4.1 Loading an FMU

The loading of FMU takes two phases: In the first phase, the model description file is parsed, while the FMU is loaded and initialized in the second phase.

FMU Model description file provides the static information of all exposed variables and model related data. FMUFd uses model description file to identify scalar variables with data types and value reference, Globally Unique Identifier (GUID) and the model name. The scalar variables are used in data flow between FMUFd and FMU model. GUID is used for validating concrete coded FMU with model description file. Model name is used to load shared object and FMI functions. The dynamic link library has the same name as the model; shared object FMI functions should also take the model name as a prefix to their functions [5].

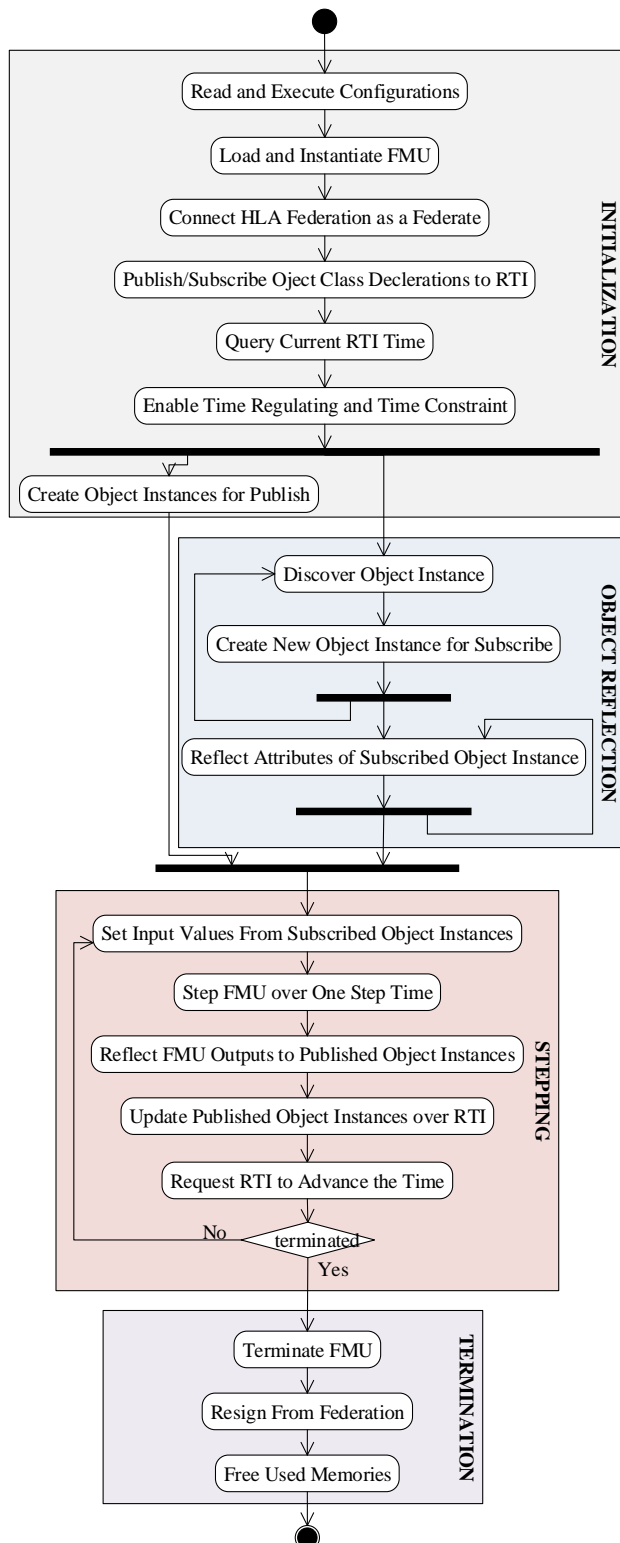

Figure 3– The FMUd Activity Diagram

The FMU related operations are developed based on the FMU SDK [11]. By using these operations, FMUd can load and use the FMU. The shared library, inside the FMU file should supply FMI Co-Simulation interface implementations. FMUd loads

those implementations automatically and then instantiates the model and gets the model instance. By then, FMU is ready to run steps over time.

## 4.2 FMU as an HLA Federate

This section describes how the FMUd can join a federation execution as a member federate.

### 4.2.1 Connect to the HLA Federation

The FOM file contains all data exchange related information of HLA Federation, including object classes and object class attributes. By using this file, the FMUd identifies the structure of each object class with attributes and data types.

The parsing process of a FOM takes two steps. First of all, the data types are parsed and stored in a map. For each type of the data, different parsing procedure is applied as each type has its special fields. For example, the size and endian information is set only for basic data types. Then, the object classes are parsed with their attributes and the data type of each attribute is retrieved from the map. If a class is derived, then its inherited attributes are obtained from its ancestors.

After parsing the FOM file, FMUd tries to connect to the federation. The federation information is provided by the user through a configuration file. The FMUd reads this file to get the federation name, path of FOM file and the name of its own federate. Then, FMUd tries to create a federation if it has not been created yet. Finally, it joins the federation.

After joining the federation, FMUd declares RTI which object classes with which attributes will be published and/or subscribed. This information is provided by the user with a SOM file. The FMUd reads the file and identifies the published/subscribed objects and informs the RTI.

### 4.2.2 Create Object Instances

There are two scenarios for creating the object instances. At the beginning of the simulation, after declaring the object classes, the FMUd creates the object class instances for publishing the FMU output parameters. The initial values of this object can be assigned by user with using the configuration files. Then, whenever an object class is discovered (new object instance is subscribed), the FMUd creates an instance of the discovered object class.

Each object contains both object class metadata and attributes. Each attribute allocates the memory with the same size as its data type. While calculating the size of a data type the padding rules are used as described in section 3.3. Although there exists some

rules, still it may not be straightforward to find the exact size of the data type. For example, fixed record data type can contain another fixed record data type and a dynamic array data type. In this case, it is not possible to find exact size of the data type without filling the exact data. Therefore, for every update, the size of the data type should be recalculated. This recalculation may have a problem regarding the performance of an application. To address this issue, the FMUFD has been designed with two restrictions:

- The array data type with dynamic cardinality is not supported by FMUFD,
- The discriminant value of the variant record data type is explicitly defined in configuration file and cannot be changed in runtime.

With these restrictions, the FMUFD calculates the size of each attribute at the beginning of the simulation and uses this size throughout the simulation. As the data can contain different data types in it, the calculation may be performed through recursion. The basic data type is the only type with known size. Whenever the recursion reaches a basic data type, the padding rules are applied. The base case of the recursion could be the code segment given in Figure 4. The *currentOffset* value is passed into recursion which holds the previously calculated offset. After recursion is finished, *currentOffset* will hold the size of the root data type.

```
if(theDataType->type ==
ObjectClass::Attribute::DataType::BasicData)
{
    int mod = theDataType->size;
    int padding = (theDataType->size
                    - (currentOffset % mod))
                  % mod;
    theDataType->offset = currentOffset + padding;
    currentOffset = newDataType->size
                  + theDataType->offset;
}
```

Figure 4 – The base condition code snapshot for calculating the padding bytes

#### 4.2.3 Update/Reflect Object Class Attribute

A complex data type can contain both big endian and little endian data types in it, independent from application computer's endian type. Therefore, before updating the object class attribute, the attribute values should be encoded to the right type of endian. Likewise, after reflecting the attribute, the value should be decoded to the computer endian type. The FMUFD always keeps the data with the same encoding of computer. By doing that, it becomes easier to use the data in an application. Whenever an attribute is needed to be updated, the attribute is encoded first then update

operation is called. Likewise, whenever an attribute is reflected, the value of that attribute is decoded first and kept in decoded form in memory.

The encode/decode operation is also executed with recursion. The basic data type is the only type with known endian type. Whenever the recursion reaches to the basic data type, the swapping operation is applied. The base case of the recursion could be the code segment given in Figure 5. The *returnValue* and *rowData* are the void\* data type values, with the same size of attribute. If the recursion is used for updating the attribute operation than *rowData* refers to the current value of the attribute, otherwise, it refers to the reflected value of the attribute. The *returnValue* refers to the encoded (or decoded) value of the attribute.

```
if(dataType.type
== ObjectClass::Attribute
::DataType::DataType::BasicData)
{
    if(currentNodeEndianType
    != dataType.endianType )
    {
        T_UINT8* returnValueOffset
        = (((T_UINT8*) returnValue )
          + dataType.offset);
        T_UINT8* rowDataOffset
        = (((T_UINT8*) rowData )
          + dataType.offset);

        switch(dataType.size)
        {
            case sizeof(T_UINT8):
                *returnValueOffset = *rowDataOffset;
                break;
            case sizeof(T_UINT16):
                *((T_UINT16 *) returnValueOffset)
                = _byteswap_ushort(*((T_UINT16 *) rowDataOffset));
                break;
            case sizeof(T_UINT32):
                *((T_UINT16 *) returnValueOffset)
                = _byteswap_ulong(*((T_UINT16 *) rowDataOffset));
                break;
            case sizeof(T_UINT64):
                *((T_UINT16 *) returnValueOffset)
                = _byteswap_uint64(*((T_UINT16 *) rowDataOffset));
                break;
        }
    }
}
```

Figure 5 – The base condition code snapshot for encoding/decoding the attribute values.

### 4.3 Running the Federate

After introducing how HLA data is de-marshalled, the next step is mapping FMU scalar variables to HLA basic data types. This mapping is performed through user configuration files. These files inform the FMUFD about which data from HLA will be set to FMU and which data from FMU will be published to HLA.

After mapping between FMU scalar variables and the HLA attributes, the stepping function can be executed.

Before running a step of FMU, the FMUFD updates each input variable of the model. The input values are obtained from an instance of related object class. If there is no instance for related object class then the FMUFD will wait for the instance of that related object.

After running a step of FMU, the FMUFD updates related attributes of the HLA objects by retrieving the values from related FMU scalar variables. Therefore, an FMU output values can be mapped to different HLA objects, which are controlled by the FMUFD. After value updates are finished, the FMUFD will request the RTI to publish those attributes.

#### 4.4 FMUFD Structure

The FMUFD is implemented as an application. Inspired from paper [14], the application is constructed with three base layers as Figure 6.

Figure 6 – the FMUFD Structure

##### 4.4.1 Presentation Layer

The presentation layer is the user interface of the application. This layer provides presentation of application, input and interaction with the user as shown in Figure 7. The plot in the figure shows the change of some parameters of the missile and target over time. By using this layer, a user can load the necessary configurations to FMUFD and observe scalar variables' value changes in real time.

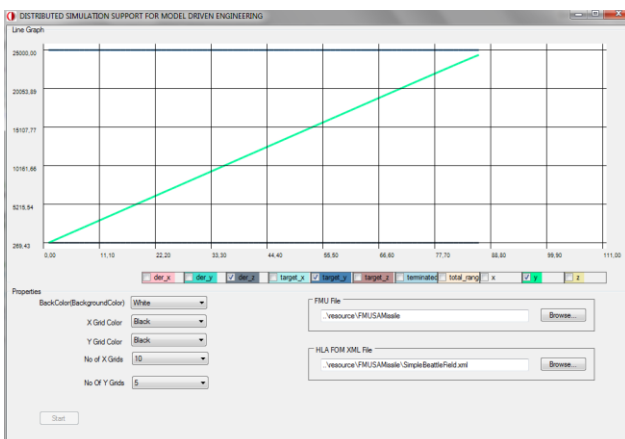

Figure 7 – The FMUFD screenshot while running the missile FMU

##### 4.4.2 Simulation Layer

The simulation layer processes the application. It includes the computation of FMI simulation and federate specific HLA object classes. Its purpose is to run FMU and generate the federate behavior.

Simulation layer is responsible for running the simulation. This layer initializes the FMU, supplies necessary inputs for FMU from HLA class instances, runs the models and publishes the model outputs over HLA distributed environment.

One of the key features of the simulation layer is to create HLA object class structure dynamically. That is, without having the real structure, simulation layer can create a void data with the same size of the structure by using FOM xml file. Then simulation layer can edit this void data parts with the same position of any object class attribute fields.

##### 4.4.3 Communication Layer

The communication layer deals with the RTI communication in order to access the object classes and interactions exchanged in the federation execution. RTI is the middleware that manages the federation execution and object exchange through a federation execution. In addition to data exchange, communication layer also supports time management service.

#### 4.5 FMUFD Capabilities

In this section, FMUFD capabilities are described in terms of HLA interface services. Data distribution management and ownership management are not used in our current implementation.

**Federation Management:** If the federation has not been created before, the FMUFD creates the federation. Then it joins the federation. Similarly, after simulation is finished, the FMUFD resigns from the federation and if there is no other federate connected to the federation, it destroys the federation.

**Declaration Management:** FMUFD informs the RTI about publishing/subscribing object classes with attributes.

**Object Management:** Whenever new object class instance is discovered, FMUFD keeps the handle for this instance and allocates memory for it. Whenever a *reflectAttributeValues* event is raised by RTI, the FMUFD check whether the object instance is discovered before. If it is discovered, FMUFD reflects the attribute values to the allocated memories of the object instance, and ignores otherwise. Whenever a *removeObjectInstance* event is raised by RTI, the FMUFD checks if the object instance is discovered before. If it is discovered, FMUFD deletes the handle of instance and frees the related allocated memory.

FMUd reflects the attribute values to the allocated memory of the object instance, ignores otherwise.

**Time Management:** FMUd works as a time regulating and time constraining federate. As the nature of the time constraint, FMUd ensures that the subscribed object model instance received reflection no less than the *currentRTITime*. Also, after each running step of the model, FMUd requests to update the federate time.

#### 4.6 Limitations

FMUd still has some limitations and constraints. First of all, HLA interactions are not supported by FMUd as there exists no corresponding logical concept in current FMI for Co-Simulation standard. Moreover, the array data type with dynamic cardinality is not supported by FMUd. Finally, the discriminant value of the variant record data type is defined at the beginning of the simulation and FMUd does not allow changing it at runtime.

### 5 Demonstration

To demonstrate the FMUd usage, a simple distributed simulation environment is developed with MAK HLA RTI [12] implementation. For this application, the RPR2-D17 FOM file developed by SISO [13] is used as a FOM file. The used HLA object classes with its parent hierarchy are shown in Figure 8.

```
HLAobjectRoot.BaseEntity.PhysicalEntity.Platform.Aircraft
HLAobjectRoot.BaseEntity.PhysicalEntity.Munition
```

Figure 8 – RPR2-D17 FOM classes used in the case study.

There are three nodes connected over an Ethernet network in this distributed simulation environment as shown in Figure 9. In the missile node, the missile co-simulation FMU (called *MissileFMUd*) is connected to distributed simulation environment as the HLA federate by using FMUd. Similar to missile PC, the aircraft co-simulation FMU is also connected to the simulation environment as a federate by using FMUd (called *AircraftFMUd*) in the target aircraft PC. The synthetic environment node is used to provide other entities in this operational setting, such as the missile launch platform, and to visualize the simulation in 2D and 3D. To this end, Presagis STAGE is used [15].

With two configuration files, one for FMU inputs and one for FMU outputs, user should supply information to the FMUd about mapping between FMU scalar variables and HLA basic data types. Therefore,

the entire hierarchy down to the basic data types should be explicitly defined for an object model.

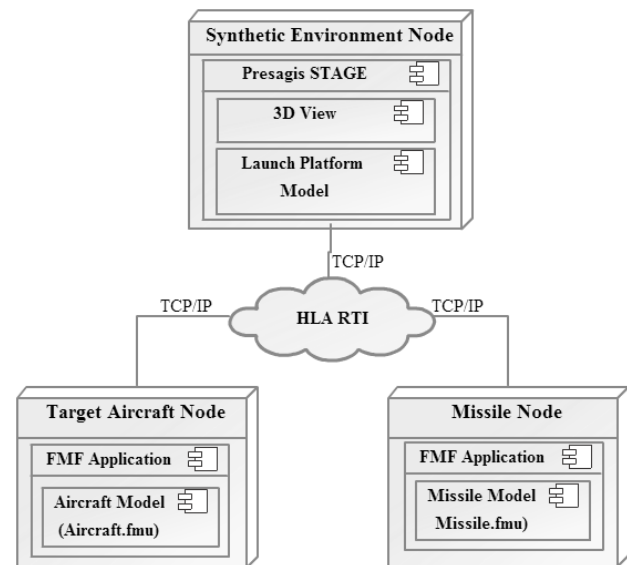

Figure 9 – The Deployment View Diagram of Simulation Environment

The example extract from a configuration file is provided in Figure 10. This example shows how the *Target\_Ecef\_X* scalar variable can be mapped with the *Aircraft* object's *Spatial* attribute's data type where data type goes down the hierarchy until it reaches the basic data type *HLAfloat64BE*. This mapping is specified for other scalar variables as well.

```
Target_Ecef_X = Aircraft|Spatial|SpatialStruct
:DeadReckoningAlgorithm-A-Alternatives
:SpatialStruct-DeadReckoningAlgorithm[DRM_FPW]
:SpatialFPStruct:WorldLocation:WorldLocationStruct:X
:HLAfloat64BEmetersperfectalways:HLAfloat64BE
```

Figure 10 – The example mapping between FMU scalar variables and HLA object class attribute data types.

With these configurations, 1500 simulation runs have been executed and performance figures for framework overhead have been measured. The median time for updating FMU parameters from HLA objects for *MissileFMUd* is 254 microseconds. Likewise, the median time for updating HLA attributes from FMU parameters for *MissileFMUd* is 356 microseconds. Measurement were taken on a computer with Intel Xeon 2.66GHz processor, 4GB DDR3 RAM and Windows 7 Pro 64bit operation system.

## 6 Conclusion

The FMI is an emerging standard for co-simulation and model exchange in Model Based Integration community. Also, HLA is a well-accepted standard for the distributed simulation. FMUfd supplies a solution for participation of FMUs that implement FMI Co-Simulation interface in an HLA Federation. Thus, a system model can be simulated as a part of an aggregate simulation of its operational setting. Moreover, this promotes a high level of reusability of system models supporting FMI.

As an alternative approach, the wrapping process may generate an FMU HLA wrapper code automatically by reading the FMU specification and generating the wrapper that knows how to translate just the specific FMU join HLA. This approach, on the other hand, is both FMU and federation specific and requires a recompile for each FMU. In our case, we aimed at recompilation free integration of FMUs to any federation via configuration files.

Finally, FMUfd is currently released in Roketsan Inc. as an in-house developed simulation infrastructure and being employed in some system development projects.

## Abstract

Simulation models play a fundamental role in the development of transmission control software. In the ideal case, the same model can be used throughout the whole development process from concept and design over implementation to system verification. The idea is to use one uniform model along this V-scheme. This leads to the requirement that simulations have to be able to run in real-time on hardware-in-the-loop platforms. On the other hand, very detailed models of some components might be needed during the early design phase.

Thus, a trade-off between modeling depth and computational performance has to be found. This may be achieved by selectively simplifying parts of the model that are prone to generating stiff sub-systems or a large number of state events.

Within this framework, the present paper introduces the Modelica simulation model of TraXon, the new modular transmission for heavy commercial vehicles by ZF. The model can be adapted to various needs by replacing components according to the required modeling depth and/or dynamical behavior.

After a brief overview of the ZF in-house Modelica libraries and the architecture of the TraXon model, some approaches and tools are described for evaluating and optimizing models with respect to real-time issues.

*Keywords:* ZF Modelica libraries; model simplification; performance analysis; hardware-in-the-loop;

## 1 Introduction

ZF is a global player in driveline and chassis technology. Being confronted with a huge variety of increasingly complex transmission concepts and continuously reduced development cycle times, simulation has traditionally been an essential part of transmission control software engineering at ZF. Detailed

models reflecting the mechanical structure of the transmission as well as the physical behavior of its actuating components are central to this task.

This paper outlines the Modelica simulation model of the new ZF TraXon transmission. Here, the principles of object-orientated modeling inherent to Modelica greatly contribute towards balancing both modeling accuracy and real-time performance. Thus, one simulation model can be used throughout the whole development process.

## 2 Usage of Modelica in ZF

### 2.1 Motivation

Modelica was introduced at ZF over 10 years ago. The main intention was to standardize the modeling methodology for transmission systems and to share modeling know-how by creating component libraries accessible throughout the company [1].

Modelica nowadays represents the standard approach for modeling and simulating of a wide range of distinct transmission systems, particularly in the context of control algorithm development. Originally starting from one single ZF Modelica Library, more than ten different context-specific libraries have been developed so far, all based on the Modelica Standard Library [2].

### 2.2 ZF Modelica Libraries

While some of the above mentioned Modelica libraries are only employed for targeted investigations regarding, e.g., shifting comfort or combustion engine dynamics, others are regularly used in almost every transmission model formulation:

- ZFLib, encompassing central gear parts such as clutches, synchronizers, table-based engine formulations, controllers, chassis models, etc. It is based on the Modelica Standard Library and also con-

tains some extensions to the components therein.

- HybridLib, including extensions for hybrid powertrains (electrical machines, battery models and complete driving strategies for hybrid vehicles).
- FluidLib for pneumatic/hydraulic actuating cylinders and valves. This library was built upon Modelica.Media and Modelica.Fluid. The separation of fluid-mechanic components and the employed media is quite useful in order to design models that can be used for both hydraulics and pneumatics.

The motivation for developing in-house libraries rather than using commercial ones stems from the following requirements:

- Adaptability of components according to internal standards, e.g., with respect to data handling and parameterization [1].
- Preservation of ZF-specific modeling know-how inside components.
- Synergy effects when modeling closely related transmission concepts.
- Models perfectly tailored to the needs of ZF.

In particular, the central libraries are widely reused among distinct transmission modeling projects, thus leading to thoroughly tested components characterized by a high degree of reliability and robustness. Dymola [3] represents the standard front-end tool. However, as Modelica is tool-independent current efforts also aim at evaluating the usability of the ZF Modelica libraries in SimulationX [4]. Then, users may choose the most suitable tool for their task.

### 2.3 Model Export

In addition to the unified modeling approach described above, also a standardized export process has been implemented. The possibility to make simulation models available on various software design and testing platforms is an essential requirement. One common software development and integration tool is Simulink [5] with its ability to export models to other platforms.

For this purpose, the Dymola-Simulink interface has been adapted in order to serve all simulation environments used at ZF, especially ZF-internal software-in-the-loop and hardware-in-the-loop platforms. One particular extension to the original interface is that different fixed-step solvers are attached to the exported models. These solvers can be selected just before running the simulation, so the user may decide whether he wants to use the Simulink

solver or one of the built-in fixed-step integrators. Furthermore, the inner simulation time step can be defined independently from the Simulink solver step size. If the inner step size is smaller than the global step size a sample and hold mechanism is implemented for in- and outputs.

## 3 The TraXon simulation model

### 3.1 TraXon – the new modular transmission by ZF

TraXon (Figure 1) is an automatic commercial vehicle transmission platform with five modules for different driving applications, satisfying the most challenging requirements. It is prepared for intelligent networking with other vehicle systems, and sets new standards in the areas of efficiency, comfort, and application diversity [6].

Figure 1: TraXon transmission

### 3.2 TraXon simulation model: overview

The modular structure of the TraXon transmission is also reflected in the structure of the simulation model. Correspondingly, the TraXon gearbox model consists of six mechanical sub-systems in series, each one associated with its own (pneumatic) actuator concept (Figure 2). In particular, these sub-systems all have a uniform connector interface and can thus easily be rearranged to model a wide spectrum of distinct transmission topologies in a consistent manner.

Figure 3 exemplifies the general structure of such a sub-system (splitter). Note that there is a clear separation between the rotational part, mimicking the torque flow through a synchronizer depending on the position of the sleeve, and the actuator, which trans-

Figure 2: TraXon simulation model: engine clutch, splitter (synchronizer), brake, main gear (dog clutch transmission with specified shifting geometry), group transmission (synchronizer) and retarder

lationally moves the sleeve according to the pressure relationships inside a two-position pneumatic cylinder.

Figure 3: Splitter part of the TraXon transmission, modeling a synchronizer actuated by a pneumatic cylinder

By extending from a common interface, different actuator concepts (e.g., electro-magnetic or electro-mechanical) and actuator formulations with varying modeling depth can thus quickly be exchanged and simulated. This is especially important when the model needs to be simplified for real-time simulations.

### 3.3 Detailed modeling approach

The master model contains all relevant physical effects of the pneumatic actuators and can be employed for detailed MiL/SiL-investigations during function development.

#### 3.3.1 Detailed actuator cylinder model

Almost all components of TraXon are actuated by pneumatic cylinders due to the fact that this kind of energy is already available on heavy trucks. The physical model of these actuator cylinders consists of replaceable variants of chamber and piston components. The most detailed piston model considers friction with stick-slip-effects. This results in high calculation effort, so the piston may also be replaced (using the “replaceable” mechanism of Modelica) by other variants building on continuous friction modeling approaches. End-stops are generally not taken into account; instead they are incorporated into the translational dynamics of actuated shifting device. This helps to reduce the number of equations without any effect on the overall behavior of the model. The detent of the piston is also modeled, assuring that the piston stays in a pre-defined position if not actuated.

Chambers are composed of a fluid volume and a translational flange, transmitting force according to the product of fluid pressure and plunger area. The latter may be constant or position-dependent as in the case of “three-position” cylinders, where the piston can be held at a center-position.

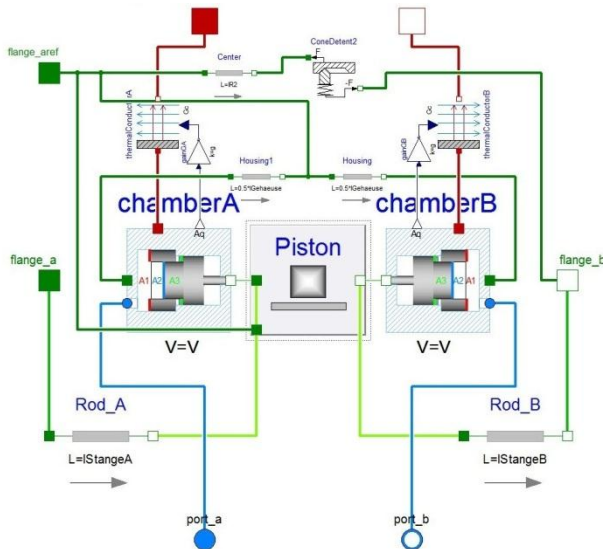

Figure 4: Detailed cylinder model using replaceable components

A major advantage here is that the modeling media are separated from the components so that the cylinder models can be used for pneumatic and also for hydraulic systems just by changing the media.

### 3.3.2 Detailed actuator valve model

The actuator valve models governing the venting behavior of the respective cylinders are divided into an electrical, mechanical and fluid-dynamic part.

The electrical part contains coil inductance and electro-magnetic force. Control signals are generated by Pulse-Width-Modulation. Simplifications are made in the magnetic part by neglecting hysteresis and using tables instead. The mechanical part consists of a translational spring-mass system for the valve tappet. End-stops are modelled and friction can be activated but is not used at the moment.

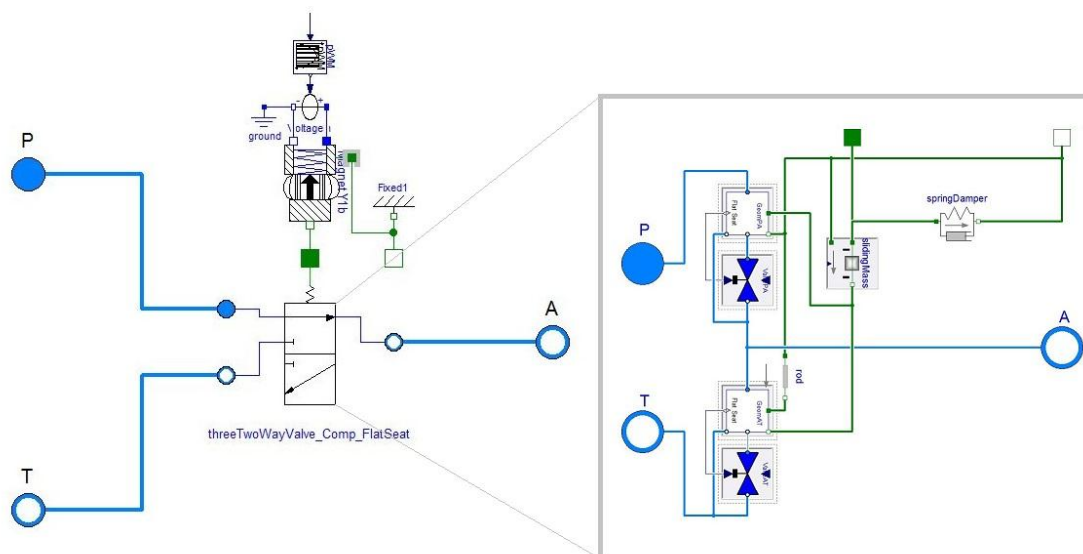

Figure 5: Detailed valve model composed of electrical, mechanical and fluid-dynamic part

The fluid-dynamic part is divided into a geometrical and a fluid flow part, both of which are replaceable. The geometrical part yields the valve opening resulting from a specific position of the tappet. Different valve seating geometries can be realized, including flat seat and ball-drill/-cone seat. The fluid flow part calculates mass flow depending on the valve opening.

Here, changing from pneumatics to hydraulics is almost as easy as in the case of cylinders. The only component that has to be replaced is the inner valve containing the equations to calculate the pressure drop. This is due to the fact that a different behavior results dependent on the compressibility of the media (compressible (e.g., air) vs. incompressible (e.g., simple oil)).

### 3.4 Simplifications made for real-time computations

Since the TraXon simulation model aims at accompanying the entire software development process, there is a special constraint: real-time capability.

To meet this challenge, certain model simplifications have to be implemented in order to guarantee a fast and robust simulation on HiL-platforms, usually employing an Euler-forward algorithm with a fixed step size of 1 ms.

In this context, extensive use is made of Modelica's inherent feature to make certain model components easily exchangeable. In particular, by declaring the above-mentioned actuator parts as replaceable, cylinder and valve formulations with different levels of detail may directly be incorporated into the model without changing the surrounding structure. This feature is especially beneficial during model simplification steps as outlined below.

### 3.4.1 Simplified actuator cylinder model

In the simplified cylinder model the plunger areas are parameterized such that the neutral position corresponds to a force equilibrium if both chambers have ambient pressure. Therefore, the detent force can usually be neglected. Friction is modeled in a velocity-dependent way in order to avoid stick-slip-events and thus the creation of many event iterations. The volumes of the in- and outgoing pipes are lumped into the dead volume of the chambers. This avoids fast dynamics due to small fluid volumes and hence leads to better numerical stability.

### 3.4.2 Simplified actuator valve model

In contrast to the detailed valve model the electro-mechanical part is replaced by a second-order transfer function. Thus, higher frequencies of the valve piston movement can be avoided. Also the generation of events is reduced by neglecting end-stops of the piston.

## 3.5 Stability analysis

If simulation has to be performed with a fixed step solver, the stability region of the integrator has to be taken into account. Facing a complex model like the one introduced before, with multiple domains interacting with each other, it is difficult to identify the critical modes of the system, i.e., those modes that do not fulfill the stability requirements because their eigen-frequencies are too fast.

To overcome this problem a MATLAB [5] tool was implemented, which visualizes all eigenmodes and eigenvectors that can be computed by linearizing the nonlinear system at certain time points of interest.

The linearizing feature of Dymola is used for this purpose. The top panel of Figure 6 shows the stability regions for the implemented fixed step solvers.

Figure 6: Eigenmode analysis tool

The blue dots show all eigenmodes in the z-space. Each dot that does not fall within the stability region of the used solver has to be investigated. At the bottom of Figure 6, the eigenvector of one selected eigenmode is shown.

This links the eigenmode to the contributing state variables and thus allows for identifying the corresponding components in the model. To enhance this feature, special states are included in all components, representing the stored energy. The eigenvectors can be “filtered” according to these energy states, making it even easier to find the components of interest. With this information, the engineer may decide to change the model structurally or to adapt some physical parameters, in order to move the eigenmodes into the stability region without modifying the dynamical behavior too much.

## 3.6 Performance analysis

A model analysis after symbolic manipulation of the underlying equations shows the differences between the detailed and simplified modeling approach as discussed above, see Table 1. Note that the number of mixed real/discrete systems of equations is drastically reduced, hence less computational effort is expected during event iterations.

	Detailed model	Simplified model
Number of mixed real/discrete systems of equations	20	4
Number of states	180	124
Number of linear systems of equations	4	4
Max. size of linear systems of equations	8	8
Number of nonlin. systems of equations	12	7
Max. size of nonlin. systems of equations	17	17

Table 1: Model analysis before and after simplification

The performance increase by using the simplified modeling approach can be seen in Figure 7. This computational load can be made visible because the translated model is running in our own simulation framework by calling the “dsblock” C-function [7], and the time needed for its execution is measured at each time step. A very important effect that can be seen in this plot is the occurrence of events and the time needed to handle them. In general, finding consistent restarting conditions after an event is a serious problem for real-time simulations as it seems that at every event handling the calculation time required is at least two times higher than the average time without an event. Due to this effect the maximum al-

Figure 7: Computational performance before and after simplification

lowed calculation effort is half the integration step size – here 0.5 ms – to avoid time overruns.

Using this analysis tool, the average time interval needed for executing one solver step can be lowered by approximately 50%. Another important effect is the reduction of state events and the parallel decrease of iteration steps necessary for finding consistent restart conditions. When using the TraXon simulation model on hardware-in-the-loop platforms this is the key to avoid overruns.

## 4 Conclusions

The use of simulation models along the entire software development process is widely implemented at ZF. A standardized way to export models to different simulation platforms has been established and the potential of the Functional Mockup Interface in this regard is currently evaluated.

Modelers can benefit from the availability of in-house Modelica libraries and components that are extensively reused in many simulation models.

For real-time applications, object oriented modeling provides an elegant way to rapidly switch between different model formulations with a varying degree of detail. This is a key feature when the model has to be simplified in order to ensure a fast and robust execution. Nevertheless, the analysis methods inside Dymola with respect to this task may be improved. In particular, an automated way for ranking model variables according to their contribution to different timescales in the model would be highly desirable.

Furthermore, the generation of events and the subsequent iteration process represents a drawback of Modelica in the context of for real-time applications.

<sup>3</sup>Volvo Group Trucks Technology

## Abstract

A linear single-track model for articulated vehicles has been implemented. The model can represent an articulated vehicle with an arbitrary number of units each with an arbitrary number of axles. Lateral and yaw dynamics are in focus but longitudinal effects in couplings are also included. In the model, tire forces are linear with respect to slip angle. The couplings between units are represented as non-linear kinematic constraints which are valid for small and large articulation angles.

Four use cases are presented: Inverse dynamics for feedforward control, frequency responses when varying parameters, steady-state evaluations and dynamic simulation. For these use cases, four parametrizations of the model are used corresponding to a tractor with a semitrailer a truck with a dolly and a semitrailer, an A-double (tractor+semitrailer+dolly+semitrailer) and an approximate version of an airport baggage carrier with five full trailers.

*Keywords: vehicle dynamics, vehicle models, articulated vehicles*

## 1 Introduction

Simple vehicle dynamics models are very useful for basic analysis, rough parameter tuning and concept studies. By keeping models simple, one gains not only simulation speed but the possibility to for example invert the model for feedforward control. A simple model is however not always simple to model.

Several modeling approaches have been used to model articulated vehicles [1], [2], [3], [4]. For simple models, it is common to simplify the coupling equations using small angle approximations. This greatly simplifies the modeling effort but also invalidates the

model for low-speed cases when articulation angles typically exceed the validity range of such an approximation. For multiple units, keeping the non-linear coupling equations usually require some kind of symbolic solver, such as Maple, Mathematica or Matlab's Symbolic toolbox. It is also common that the modeling is done for a specific vehicle combination with little room for extending to more units without reformulating the model.

Creating the model using Modelica one does not have to explicitly solve all equations and thus the model formulation can be kept simple while letting the Modelica tool take care of equation solving. Furthermore, by vectorizing the model with respect to the number of units and axles the model equations does not have to be expressed with a specific vehicle combination in mind, leaving that to the specific implementation.

## 2 Model description

A description of the model equations and structure is presented here. For brevity and readability of code snippets, `vector()` and `matrix()` function calls and some full library paths are left out. MSL is used when models are taken from the Modelica Standard Library, mainly from `Modelica.SIunits` and `Modelica.Blocks`.

### 2.1 Assumptions

As is normal for single-track models, the two tires on an axle are lumped as a single tire in the middle of the axle. Coupling points are assumed to not transfer torque between units. Slip angles are assumed to be small such that  $\tan \alpha \approx \alpha$ .

While the model accepts a variable input velocity,

typical longitudinal effects such as load transfer are not taken into account.

## 2.2 Parameter and variable structure

Parameters describing positions on the vehicle are all expressed relative to the first axle of the corresponding unit. This includes axle positions, center of gravity, c.g., positions and coupling point positions. Figure 1 shows the position parameters for a unit. Since states

Figure 1: Geometric parameters of unit  $i$ .  $A_i$  and  $B_i$  are the distances from the first axle to the front and rear coupling points, respectively.  $X_i$  is the distance from the first axle to center of gravity.  $L_{i,j}$  is the distance from axle 1 to axle  $j$  on unit  $i$ .

are defined at the center of gravity of each unit, position parameters are recalculated relative to this, e.g.  $A_{cog} = A - X$ .

Parameters and quantities related to axles, such as tire forces and axle positions, are defined as matrices with dimensions  $[nu, na]$  where  $nu$  is the number of units in the combination and  $na$  denotes the maximum number of axles on any of the units. If the number of axles on a unit is less than  $na$  the unused elements will be set to zero and are thus disregarded. Parameters and quantities related to units, such as motion states and masses, are defined as vectors of length  $nu$ .

## 2.3 Tire forces

Given the small angles assumption, the slip angle for a single tire is defined as

$$\alpha = \frac{v_y + L_{cog}\omega_z}{v_x} - \delta \quad (1)$$

where  $L_{cog}$  is the distance from the center of gravity to the axle that is being considered,  $v_y$  and  $\omega_z$  are the lateral velocity and yaw rate of the unit in question and  $\delta$  is the steering angle. In the model code, the slip angle matrix for all axles is defined as

---

```
alpha = ((vy*ones(1,na)
+Lcog.*(wz*ones(1,na))
./(vx*ones(1,na))-delta);
```

---

The lateral tire forces can then be calculated as

---

```
Fyw = -C.*alpha;
```

---

where  $C$  is the axle cornering stiffness matrix. Together with the longitudinal forces,  $F_{xw}$ , the tire forces can be transformed to the vehicle coordinate system with the steering angle  $\delta$

---

```
Fx = Fxw.*cos(delta)-Fyw.*sin(delta);
Fy = Fxw.*sin(delta)+Fyw.*cos(delta);
```

---

A variable  $F_{xd}$  is defined as the drive force needed at each driven axle to maintain the input velocity. This force is applied at each driven axle:

---

```
for i in 1:nu loop
  for j in 1:na loop
    if driven[i,j] then
      Fxw[i,j]=Fxd;
    else
      Fxw[i,j]=0;
    end if;
  end for;
end for;
```

---

This force is implicitly determined to satisfy the rest of the model equations.

## 2.4 Coupling constraints

The constraints in the couplings state that the global velocity vector of the rear coupling on the unit in front should be the same as that of the front coupling point on the unit behind. The Modelica language allows for a series of equations to be defined using for loops. Here, the constraint that the velocities at the front coupling of unit  $i$  should be the same as that of the rear coupling on unit  $i-1$  is defined by looping over all the couplings:

---

```
for i in 1:nu-1 loop
  vx[i+1] = vx[i]*cos(theta[i])
    -(vy[i]+Bcog[i]*wz[i])*sin(theta[i]);
  vy[i+1]+Acog[i+1]*wz[i+1]=
    (vy[i]+Bcog[i]*wz[i])*cos(theta[i])
    +vx[i]*sin(theta[i]);
end for;
```

---

Equations for the coupling forces are not formulated explicitly, the velocity constraints in the coupling to-

gether with force and moment balances gives enough information for an implicit calculation. Figure 2 shows how the coupling cut forces are applied to the different units affected by the coupling. The forces

Figure 2: Example of cut forces in coupling between unit i (front) and i+1 (rear)

in each coupling are defined in the coordinate system of the front unit which it affects with negative sign. The rear unit in the coupling is affected by the forces with positive sign transformed by the articulation angle. So  $F_{cx}[i]$  pulls rearward on unit i and  $F_{cx}[i] \cdot \cos(\theta[i])$  pulls forward on unit i+1. Similarly,  $F_{cy}[i]$  pulls in the negative y direction (rightwards) on unit i and  $F_{cy}[i] \cdot \cos(\theta[i])$  pulls towards the left on unit i+1.

## 2.5 Steady state mode

To simplify steady-state analysis, substitute parameters are defined for each state derivative:

```
MSL.Acceleration[nu] d_vx;
MSL.Acceleration[nu] d_vy;
MSL.AngularAcceleration[nu] d_wz;
MSL.AngularVelocity[nu-1] d_theta;
```

If the model is to be run in steady-state, all derivatives are set to zero. For dynamic simulations they are set to the derivative of their corresponding state variable:

```
if steadystate then
  d_vx=zeros(nu);
  d_vy=zeros(nu);
  d_wz=zeros(nu);
  d_theta=zeros(nu-1);
else
  d_vx=der(vx);
  d_vy=der(vy);
  d_wz=der(wz);
  d_theta=der(theta);
end if;
```

## 2.6 State equations

By using matrices and vectors, the state equations can be formulated as matrix equations for the entire vehicle combination instead of writing separate equations for each unit. In the axle force matrices, a row,  $i$ , contains all the axle forces on unit  $i$ . To get the force sum on each unit, the force matrix is multiplied by a column vector of ones of length  $n_a$ :

$$\begin{bmatrix} F_{y,11} & \cdots & F_{y,1n_a} \\ \vdots & \ddots & \vdots \\ F_{y,n_u1} & \cdots & F_{y,n_un_a} \end{bmatrix} \begin{bmatrix} 1 \\ \vdots \\ 1 \end{bmatrix} = \begin{bmatrix} F_{y,11} + \cdots + F_{y,1n_a} \\ \vdots \\ F_{y,n_u1} + \cdots + F_{y,n_un_a} \end{bmatrix} \quad (2)$$

For coupling forces column vectors  $[F_{cx}; 0]$  and  $[F_{cy}; 0]$  are defined for the rear coupling forces, the 0 element meaning no rear coupling force on the rear-most unit. Similarly, vectors  $[0, F_{cx}]$  and  $[0, F_{cy}]$  are defined for the front coupling forces where 0 here means no front coupling force on the first unit. Then, the force balance equations for the whole combination can be written as a matrix equation using element-wise multiplication. The lateral and longitudinal force balances are written as:

```
ay=d_vy+vx.*wz;
m.*ay=Fy*ones(na,1)-[Fcy;0]
+[0;Fcx].*sin([0;theta])
+[0;Fcy].*cos([0;theta]);
```

```
ax=d_vx-vy.*wz;
m.*ax=Fx*ones(na,1)-[Fcx;0]
+[0;Fcx].*cos([0;theta])
-[0;Fcy].*sin([0;theta]);
```

The moment balance around the yaw axis is done in the same way with the added moment arms for the different forces:

```
I.*d_wz=Lcog.*Fy*ones(na,1)
-Bcog.*[Fcy;0]
+Aco.*([0;Fcx].*sin([0;theta])
+[0;Fcy].*cos([0;theta]));
```

where  $A_{cog}$  and  $B_{cog}$  are the distance from c.g. to the front and rear couplings, respectively and  $L_{cog}$  is the distance from c.g. to each axle.

## 2.7 Inputs

The inputs to the model are the steering angles at all axles and the velocity of the first unit.

```
input MSL.RealInput[nu,na] delta_in;
input MSL.RealInput vx_in;
```

Due to the kinematic constraints in the coupling, the derivative of the  $vx\_in$  input will be needed. To allow velocity as input when exporting the model, the derivative of  $vx\_in$  is set to zero with annotated derivatives using a `QuasiStatic` function from the `Modelon` library:

```
vx[1] =
  max(0.1, QuasiStatic.scalar(vx_in));
```

The output from the `QuasiStatic.scalar(vx_in)` function has the same value as  $vx\_in$  but with zero derivative. Here, the velocity is also set to be minimum 0.1 to protect sideslip calculations from division by zero.

### 3 Use cases

Four use cases are presented as examples. For each use case a different vehicle combination is used to show how the model can be parametrized for different vehicles.

A tractor-semitrailer model is inverted for feedforward control, a truck-dolly-semitrailer is linearized and its frequency response is studied, a tractor-semitrailer-dolly-semitrailer is run in steady-state to evaluate its off-tracking characteristics and a five-trailer airport baggage carrier is run in a dynamic simulation. Figure 3 shows the four vehicles used.

Figure 3: The four vehicle combinations used.

The Functional Mockup Interface, FMI, allows modeling and simulation to be performed in separate tools. Model development has been done in Dymola and all simulations and plotting are done in Matlab/Simulink using FMI Toolbox. The only parameters that need to be set before exporting models are the `steadystate` setting and the number of units,  $nu$ , and axles,  $na$ , as they change the structure of the model. Other parameters such as axle positions and cornering stiffnesses are free to set when using the exported model.

### 3.1 Inverse dynamics

By using the `InverseConstraints` block in the Modelica Standard Library, the inverse dynamics of the model can be solved for. To use the model for feedforward control, we select the lateral acceleration  $a_y$  of the first unit as input and the steering angle at the front axle  $\delta_{1,1}$  as output. Figure 4 shows the block diagram of the inverse model.

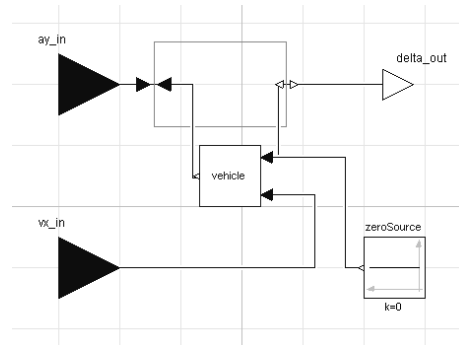

Figure 4: Block diagram of inverse model. Inputs to the model are lateral acceleration and longitudinal velocity at the first unit. Output is the required steering angle at the first axle.

To test the inverted model, a triangular acceleration signal of 0.2 Hz frequency and  $2 \text{ m/s}^2$  amplitude is sent as input. The velocity is 50 km/h. The steering output from the inverted model is then input to a model with normal causality to verify that the lateral acceleration achieved will be correct. Figure 5 shows that the lateral acceleration output from the controlled model is indeed the same as the desired lateral acceleration input. The resulting steering command is shown in figure 6.

Figure 5: Desired lateral acceleration input and output from vehicle controlled with steering output from inverted model.

Figure 6: Steering angle from inverted model.

### 3.2 Frequency response

The model can easily be linearized to find the frequency response. An important use case for this is to find how different parameters affect the frequency response. Here, the coupling position between the tractor and the trailer is varied to show how this affects the stability of the vehicle combination.

The truck-dolly-semitrailer combination is linearized for straight forward driving at 80 km/h. Figure 7 shows the baseline gain from steering angle to the yaw rates of the different units in the truck-dolly-semitrailer combination.

Figure 7: Gain from steering angle at the front axle to the yaw rates of the different units for the baseline parametrization of the truck-dolly-semitrailer combination.

Often the rearward amplification is an important measure of vehicle performance. This is defined as the gain from the first unit yaw rate to each of the towed units' yaw rates. Figure 8 and figure 9 show how the rearward amplification of the dolly and semitrailer changes as the coupling position on the truck is changed. The baseline position is 0.53 m behind the rear axle. As the coupling moves rearward the amplification increases.

Figure 8: Yaw rate gain from first unit to second unit when moving coupling position on first unit. Coupling further rearward (negative adjustment) gives higher amplification of yaw rate.

Figure 9: Yaw rate gain from first unit to third unit when moving coupling position on first unit. Coupling further rearward (negative adjustment) gives higher amplification of yaw rate.

### 3.3 Steady-state off-tracking

Off-tracking is an important property of a vehicle with trailers. It is usually defined as the difference in curve radius between the towing unit and the trailers. In the model, the instantaneous curvature is calculated for all axles as

```

for i in 1:nu loop
  for j in 1:na loop
    curvature[i,j] = wz[i]
    /sqrt((vy[i]+Lcog[i,j]*wz[i])^2
    +vx[i]^2);
  end for;
end for;

```

To show how off-tracking varies with vehicle speed, the vehicle is driven at a constant curve radius of 100 m for velocities from 1 to 80 km/h. Figure 10 shows how the curve radius of the last axle of each trailer compares to that of the first axle on the tractor. The typical

characteristic is that trailers track cuts into the curve at low speed due to vehicle kinematics and geometry. At high speed the trailers track a larger curve radius due to the increased lateral load causing higher sideslip.

Figure 10: Curve radius of the first tractor axle and the last axle of each towed unit for varying velocity.

Off-tracking for a fixed vehicle speed also varies with the curve radius of the first unit. To study this, the vehicle is run at a fixed speed of 10 km/h and curve radius of the first unit varies from 15 to 100 m. Figure 11 shows how off-tracking varies with the curve radius of the first axle. At this relatively low speed, vehicle kinematics cause more inward off-tracking at smaller curve radii.

Figure 11: Off-tracking of the last axle of each towed unit in the A-double. First unit speed is fixed and curve radius varies. Positive off-tracking is defined outwards in the curve.

### 3.4 Dynamic simulation

The baggage carrier is simulated with a single period sine steering input of  $5^\circ$  amplitude and 0.3 Hz frequency at 18 km/h. Figure 12 shows the yaw rates of all the units in the airport baggage carrier and figure 13 shows the position of each axle.

The parameters are only approximated and are not measured or estimated from a specific real vehicle.

Figure 12: Yaw rates of all the units in the baggage carrier train

Figure 13: Positions of each axle in the baggage carrier train.)

The simulation results show that the model can represent multi-trailer vehicles without additional modeling effort.

## 4 Conclusion

This work shows that Modelica is useful for formulating simple vehicle models. Using Modelica, articulated vehicle combinations with arbitrary number of units and axles can be modeled with the same level of abstraction as when modeling a non-articulated single-track vehicle model. Tool independent export and import possibilities within the Functional Mockup Interface greatly simplifies the use of models like this in control design and concept studies.

By incorporating simple-but-relevant models together with higher fidelity models in development processes infeasible concepts can be ruled out early and only the most promising ones can be carried on to more detailed analyses.

## Abstract

Considering the specific case of the multibody modelling of a racing motorbike, where the rigid model of the rear swingarm has been replaced with a flexible one, a general approach to flexible multibody systems modelling in Modelica is presented in this paper. In particular, the steps required to generate the model of a flexible body starting from a FEM analysis, performed with commercial packages, are detailed. Simulations results are shown with reference to a sudden braking and to a series of impacts with curbs. In this last case, an unstable behaviour occurred when considering the flexible component, which is currently under investigation.

*Keywords: motorcycle dynamics; flexible multibody systems; finite element method; floating frame of reference; Craig-Bampton method.*

## 1 Introduction

Object-oriented modelling, favoring a real modular and multi-domain approach, has been recognized as a fundamental tool for the mechatronic design, requiring an integrated approach to mechanical, electronic and control design [1]. In this respect, even if multibody dynamics is frequently just one of the physical domains involved, the simulation of flexible multibody systems plays an important role.

On the other hand, in real applications, the task of modelling distributed flexibility cannot be addressed without the help of finite elements (FE) codes, in order to describe complex geometries and material properties. Moreover, for the sake of efficiency of numerical simulation, the huge number of nodal coordinates introduced by FE modelling, must be reduced to a much smaller number of modal coordinates, for example through the classical Craig-Bampton method [2].

Two commercial packages exist that pre-process the output of FE codes to get the Modelica model of a

flexible body, one has been developed by the German Aerospace Center (DLR) [3], the other has been developed by Claytex Services Ltd.

The DLR FlexibleBodies library provides several Modelica classes, namely a flexible beam model (Beam), an annular plate model (AnnularPlate), a thermoelastic plate (ThermoElasticPlate) and a model for general flexible bodies exported from FE codes (ModalBody). The results of the FE analysis performed by several general purpose codes are first processed by another commercial code: FEMBS, implementing modal reduction in a two-step process. Guyan or Craig-Bampton reduction methods are applied in the first step to keep the flexible body input file to FEMBS small, while in the second step the modes in the frequency range of interest for multibody simulation are selected. The reduced modal representation is then stored in a Standard Input Data (SID) file [4, 5], an object-oriented data structure developed to define a standard format to exchange data between FE and MBS codes. When a ModalBody class is instantiated the user has to specify the name of the SID file containing the modal description of the body, which also stores the original mesh of the FE model, used by Dymola to perform the animation of the simulated motion of the flexible body.

The Claytex library generates directly the Modelica model of a flexible body from the output of the model reduction process performed by three FE codes: namely Nastran, Genesis and Abaqus.

Object-oriented modelling of general flexible multibody systems has been also described in [6] (up to the Modelica code), based on the parameters of the flexible body computed by FEM packages, stored in an ASCII file and read by a parsing tool. The model also maintains the efficient choice of the generalized coordinates implemented in the Modelica standard (rigid) multibody library. Thus, when a body is a component of a tree structure, the motion of the local Floating Frame of Reference (FFR) [7] is actually calculated by

propagating of the kinematic quantities from the root of the tree while, in the case of floating bodies, the body itself is a root, introducing its own generalized coordinates for position and orientation.

In this paper, the above mentioned approach is applied to the multibody model of a racing motorbike, where a flexible model of the rear swingarm has been considered.

First, a rigid multibody model of the motorbike has been developed, with the aim of providing forces and torques applied to the frame and to the swingarm for a following FEM structural analysis, performed for the sake of mechanical design validation. As reference simulation scenarios a sudden braking and a series of impacts with obstacles (curbs) have been considered. Then, the rigid model of the rear swingarm has been replaced with a flexible one and the simulation results have been compared.

In view of the particular simulation experiments considered only limited differences were expected, particularly appreciable during the simulation of impacts. On the other hand, the simulation of the motorbike with a flexible swingarm showed an unstable behaviour in the case of subsequent impacts, largely due to a poor performance of the virtual driver, but undoubtedly induced by swingarm flexibility, since the said behaviour in the rigid case did not occur.

The paper is organized as follows. In Section 2 the rigid multibody model of the motorbike is described, including the simulation scenarios and the related results, moreover, the simulation results are compared to experimental results obtained on the real bike. Section 3 explains the flexible multibody modelling approach used in this paper, describing the adopted theoretical formulation and the most relevant characteristics of the Modelica flexible body model. Further, it describes the procedure which leads to obtain flexible body models in Modelica. In Section 4 the flexible model of the rear swingarm is described, the procedure outlined in the previous section is adopted to obtain a flexible model of the body, then, in Section 5 the previously described simulations are repeated and the results are compared with respect to the rigid model. Section 6 concludes the paper.

## 2 Rigid multibody motorbike model

A rigid multibody model of a racing motorbike, built by RobbyMoto Engineering S.r.L., has been first developed (Fig. 1).

Since the considered scenarios were a sudden brak-

Figure 1: Model of the motorbike.

Figure 2: Scheme of the Modelica model of the motorbike.

ing and a series of impacts with obstacles (curbs), the model was not intended to simulate the dynamic behaviour of the motorbike in curves, but a steering degree of freedom was anyway provided, in order to represent the intrinsically unstable behaviour of the vehicle. The adopted tyre model accounted for lateral forces and roll angle, thus a tilt control was required.

The rigid motorbike model is made up entirely by components of the standard Modelica multibody library, except for the wheel/road interaction model and the virtual driver, taken from [8, 9]. The main components are:

- Main frame,
- Front suspensions,
- Rear suspended *Pro-Link* swingarm,
- Wheels and wheel-road interaction,
- Virtual driver: a simple vehicle stabilizer, acting on the front steer and controlling the tilt angle.

and the scheme of the Modelica model is shown in Fig. 2.

It must be pointed out that the suspension mechanism includes two interconnected planar kinematic loops, which must be carefully modelled in order to avoid singularities. In this respect, the Modelica multi-body library provides some aggregate joints implementing an analytic solution of the loops closure equations [10]. In our case, a Revolute-Revolute-Revolute (RRR) joint is used to solve one of the loops, as shown in Fig.4, which also inherently breaks the second one, hence there is no need to use another aggregate joint for the second loop. Figure 3 shows a simplified scheme of the planar loop and how it is realised in the real motorbike.

Figure 3: Planar loop.

In view of the simplicity of the considered simulation scenarios, a linear model of the tyre/road interaction has been adopted [8]. The longitudinal force is thus computed as a linear function of the longitudinal wheel slip, and the lateral force is computed as a linear function of the tire sideslip angle and of the roll angle.

Aerodynamic drag forces have been also taken into account, calculated as:

$$F_a = S_f C_z V^2$$

Figure 4: Model of the kinematic planar loop.

Where  $F_a$  is the aerodynamic force applied in the pressure center of the bike, placed 20 cm above the center of mass and biased 10 cm on the front, according to [11]. The front section of the bike is defined as  $S_f$ , the aerodynamic coefficient  $C_z$  is calculated from experimental results ( $C_z = 0.45$ ), and  $V$  is the ground speed of the vehicle. The drag force is shown in Fig. 1 as a green horizontal arrow applied to the pressure center.

## 2.1 Simulation of a braking

In this subsection, the results obtained by simulating a braking are compared to experimental data.

The experiment starts with the bike moving on a straight line at 215 km/h, then, a constant braking torque of 280 Nm is applied to the front wheel for 4 seconds, according to the pressure observed on the front brake of the real bike. While braking, the pilot weight is applied 70% on the front handlebars and 30% on the saddle.

Figure 5 shows two screenshots of the simulation before and during the braking manoeuvre, while Figs. 6 and 7 compare the simulated and experimental speeds and the elongation of the suspensions, respectively. It must be pointed out that the distribution of the driver weight in the Modelica model is constant during the entire simulation, while the distribution of the weight load in the experiment highly depends on the longitudinal acceleration, thus, the front suspension displacement is slightly different between model and experiment before the braking manoeuvre. The comparison between simulation and experiment is more significant in the first part of the transient, say the first 2 seconds, because in the last part the driver enters a curve and starts releasing the brake handle. Anyway, the simulated results appears to be in quite good accordance with the experimental data.

Afterwards, the forces and torques acting on the

Figure 5: Screenshots of the simulation before and during the braking.

frame and rear swingarm (Fig. 8) have been recorded from the simulation, in order to identify the stress peak and the actual values of loads to be used during a FEM analysis.

## 2.2 Impacts with curbs

In a second simulation experiment a series of impacts with curbs has been considered.

Curbs have been modeled as sawtooth obstacles (Fig. 9) placed on the road surface, every sawtooth has an height of 2 cm and a width of 20 cm, in order to reproduce the real curbs of most racetracks. To this aim, the road model described in [8] has been modified in order compute the quote of the road, given the position of the wheel. Since the driver weight distribution was impossible to estimate in this experiment, the whole load (70 kg) was placed on the saddle. The forces and torques acting on the frame and rear swingarm have been exported for a following FEM analysis step, Fig. 10 shows vertical forces exchanged between rear arm and main frame in the hinge.

Figure 6: Speeds during braking.

Figure 7: Front and rear suspension elongation during braking.

## 3 Flexible multibody modelling in Modelica

The object-oriented modelling paradigm implemented by the Modelica language requires a description of the dynamics of a flexible body in terms of *local* variables, while the interaction between different bodies has to be described using the *connectors* of the standard Modelica multibody library [10]. In turn, a local description of a body's dynamics naturally calls for a floating frame of reference (FFR) approach [7], which is currently the most widely used method in computer simulation of flexible multibody systems.

In the FFR formulation, each body is attached to a moving frame of reference undergoing large (rigid) motion, while the (small) elastic displacements are obtained in local coordinates with respect to the reference frame. Thus, the position (in local coordinates) of a point on a flexible body, see Fig. 11, is given by:

$$\bar{\mathbf{u}} = \bar{\mathbf{u}}_0 + \bar{\mathbf{u}}_f, \quad (1)$$

where  $\bar{\mathbf{u}}_0$  is the “undeformed” (i.e., rigid) position vector and  $\bar{\mathbf{u}}_f$  is the deformation contribution to position (i.e., the deformation field).

If small elastic deflections are considered, according to the classical Rayleigh-Ritz method [12], the infinite dimensional deformation field on the body can

Figure 8: Forces acting on the rear swingarm hinge during braking.

Figure 9: Curbs model.

be approximated by a functional basis space with finite dimension, say  $M$ , so that the vector  $\bar{\mathbf{u}}_f$  can be expressed by the finite dimensional product

$$\bar{\mathbf{u}}_f = \mathbf{S}\mathbf{q}, \quad (2)$$

where  $\mathbf{S}$  is the  $[3 \times M]$  shape functions matrix (i.e., a matrix of functions defined over the body domain and used as a basis to describe the deformation field of the body itself) and  $\mathbf{q}$  is the  $M$ -dimensional vector of deformation degrees of freedom, or *modal* coordinates. The representation of a generic flexible body in the world reference frame requires then  $6 + M$  d.o.f.: 3 corresponding to the rigid displacements  $\mathbf{r}$ , 3 to the undeformed body orientation angles  $\theta$  and  $M$  to the modal coordinates  $\mathbf{q}$ .

Starting from eqs. (1,2) and accounting for the elastic properties of the material and for the mass distribution, the generalized Newton-Euler equations for a generic unconstrained flexible body, formulated with respect to the FFR, can be derived in [13, 7, 14, 15, 5, 16], and developed up to the Modelica code in [6]. It must be also pointed out that the efficient choice of the generalized coordinates, implemented in the Modelica standard (rigid) multibody library, can be maintained. Thus, when a body is a component of a tree structure, the motion of the FFR is actually calculated by propagation of the kinematic quantities from the root of the tree while, in the case of floating bodies, the body itself is a root, introducing its own generalized coordinates for position and orientation.

Figure 10: Vertical forces acting on the rear swingarm hinge during impacts with curbs.

Figure 11: Floating reference frame.

In the case of simple geometries, such as beams [13], the set of data required to implement the flexible body dynamic equations, summarized in Table 1, can be determined analytically, but in more general cases the use of finite elements (FE) computer codes as preprocessors is necessary. In this last case the huge number of *nodal* coordinates must be reduced to a much smaller number of modal coordinates, through the classical Craig-Bampton method [2] or other recently proposed methods [17, 18, 14, 19].

The Modelica model of a general flexible body: FEMBody, is characterized by an array of  $N_c$  multibody connectors, while the data in Table 1 have been suitably collected in the Modelica record BodyData. The record is defined as replaceable:

```
replaceable parameter FEMData.BodyData
data;
```

so that it is possible, by exploiting the features of the Modelica language, to assign a different data record to each FEMBody instance, by simply replacing the record in the model declaration:

```
FEMBody FlexPendulum(redeclare
FEMData.PendulumData data,
alpha=0.005,
```

Table 1: Flexible body data.

$M$	Number of deformation d.o.f.
$I^1, I^2, I_i^3, I^4, I_i^5, I^6, I^7, I_i^8, I_{ij}^9, I_{ij}^{10}, I_{ij}^{11}$	Inertia invariants
$D_e, K_e$	Structural damping and stiffness matrix
$N_c$	Number of connectors
$S_i, \hat{S}_i$	Slices of the modal matrix of connectors d.o.f.
$\bar{u}_{0i}, \bar{A}_i$	Undeformed position and orientation of connectors

beta=0.005,  
d=1);

where alpha, beta, d are the parameters defining the damping matrix (Rayleigh coefficients).

The process of generation of the flexible body data record is schematized in Fig. 12.

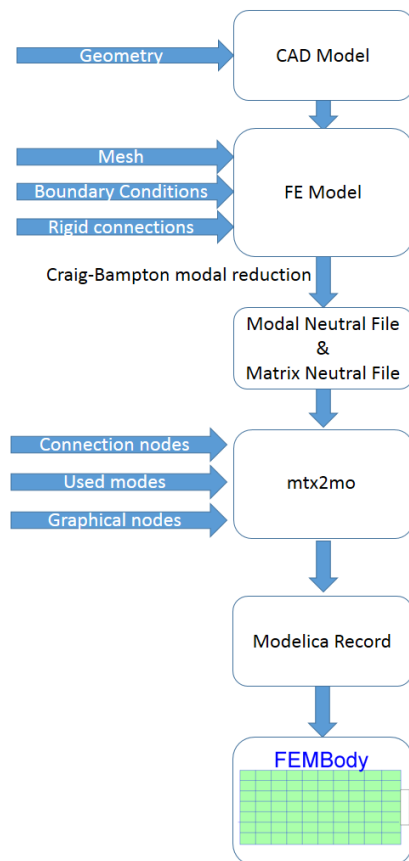

Figure 12: Flexible body data generation.

First, a FE model of the body is developed based on 3D CAD model (often inherited from design phase).

Then, a FEM analysis is performed, essentially consisting in an eigenfrequency analysis followed by a modal reduction step, generally based on the Craig-Bampton method.

The results of the FEM analysis are stored in a bi-

nary Modal Neutral File (.mnf)<sup>1</sup>, which must be then translated into an ASCII file, usually with extension .mtx, containing the same data in a readable format. This step can be performed through the Adams/Flex tool, a package included in the MSC.Adams suite, which allows to inspect the .mnf file and export the content in ASCII format.

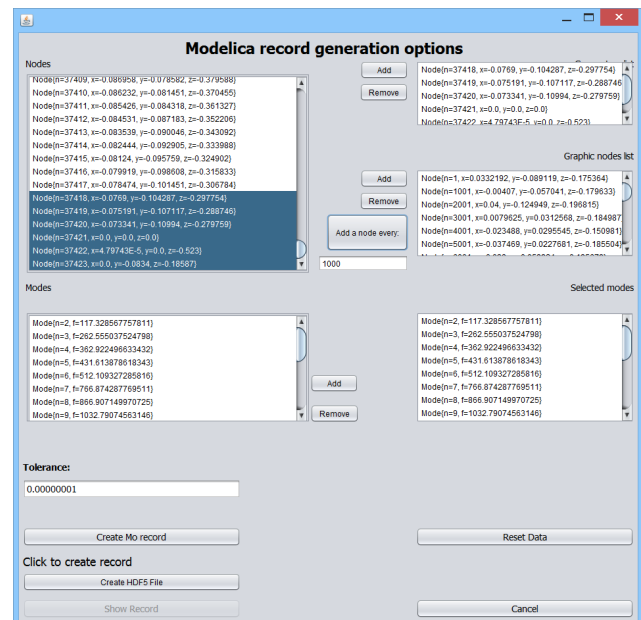

Figure 13: mtx2mo: Graphical User Interface.

The file containing the Modelica record of flexible body data is finally generated by a parsing software tool, named *mtx2mo*, written in Java<sup>2</sup> (a screenshot of the tool is reported in Fig. 13). This tool reads the content of the .mtx file and translates it into the Modelica syntax, moreover, it allows the user to choose:

- the eigenmodes to be considered;
- which nodes of FE processing are selected as the position of the multibody connectors;

<sup>1</sup>The inertia invariants  $I^{10}$  and  $I^{11}$ , are not a direct result of the analysis and are not stored in this file, they are computed by two Modelica functions from invariants  $I^8$  and  $I^9$ , as detailed in [6].

<sup>2</sup>The tool could be implemented also in C or Modelica.

- how many FE nodes are selected for the 3D graphic rendering of the model.

The described approach thus avoids the preprocessing stage adopted by the DLR FlexibleBodies library, which requires the models to be processed by FEMBS in order to obtain the SID file.

Figure 14: FE model of the swingarm.

## 4 Modelling a flexible swingarm

Figure 14 shows the FE model of the swingarm, realised with the Patran/Nastran suite by MSC.Software.

Figure 15: Multi-point constraint.

The swingarm is characterized by three connection points, so three virtual nodes have been defined in the FE geometry: one in the center of the frame pivot, one in the lower triangle pivot, and one in the center of the wheel hub. The internal surfaces of bores have been associated to this massless nodes by RBE2 rigid multi-point connections, namely, every node of the mesh located on the surface of the holes is rigidly connected to the virtual node, so that the motion of all dependent nodes is constrained by the motion of one node. Figure 15 shows the rigid connection between nodes in the front bore.

The boundary conditions were assigned in order to reproduce the hinge acting on the rear swingarm: all translations and two rotations were fixed for the pin

connecting the swingarm to the mainframe, while all the other nodes were free to move. A free-motion eigenvalue resulted from the FEM analysis, with a very small absolute value ( $1.2 \cdot 10^{-3}$  Hz), neglected in the generation of the Modelica model.

The first 20 eigenmodes were retained from the FEM analysis, with eigenfrequencies ranging from 117.3 Hz to 3585.6 Hz, the first eigenmode is shown in Fig. 16.

Figure 16: First torsional eigenmode.

It must be pointed out that structural damping is accounted in the flexible body model by means of the Rayleigh coefficients, which are difficult to estimate and are often the result of an averaging on the damping ratios of different modes. In this work the coefficients are chosen as  $d = 1$ ,  $\alpha = \beta = 0.005$ .

The Modelica model of the flexible swingarm is shown in Fig. 17. Note that, for the sake of modularity, the connectors of the flexible body are stored in a vector, hence it is not possible to distinguish the connections in the graphical layer of the model.

It must be also pointed out that the RRR joint used in the rigid case to manage the kinematic loop is no longer required, as the flexibility of the body inherently breaks the loop.

A relative position sensor has been also introduced, with the aim of sensing the deflection of the rear wheel hub with respect to the position of the rear wheel bore in the undeformed configuration.

Figure 17: Modelica model of flexible swingarm.

## 5 Simulation results with a flexible swingarm

Figure 18: Displacement of rear wheel hub in braking.

Figure 19: Vertical position of vehicle mass center during braking.

The experiments reported in Section 2 have been repeated with the flexible swingarm model.

Figure 18 shows the deflection of the rear hub measured by the above mentioned relative sensor. During the braking manoeuvre the swingarm deflects under the load on the rear part of the bike, starting from a value of 0.16 mm on the vertical axis before braking. A lateral displacement is also measured, due to the imprecise virtual driver, which cannot maintain the motorbike perfectly vertical. Although the swingarm deflection is small, it anyway affects the overall geometry of the vehicle.

In Fig.19 the quotes of the mass center of the overall vehicle are shown, in the rigid and flexible case. During the braking, the weight and the inertia loads mainly impact on the front wheel, while the rear suspension reaches an equilibrium where poor forces are applied.

Forces and torques applied on the frame do not change significantly with respect to the rigid model, in Fig. 20 the vertical forces in the rear hinge are compared between the rigid and the flexible case at the beginning of the manoeuvre. As expected, the dif-

ferences ( $\approx 3\%$  of the maximum value) are scarcely appreciable in the transients, and the deformation values are in good accordance with the static FE analysis (Fig. 21), in which the same loads (extracted from the multibody analysis) are applied.

Figure 20: Vertical forces at the beginning of braking manoeuvre.

Figure 21: FEM static analysis of rear arm displacement.

During the simulated impacts with curbs the forces acting on the wheel, and consequently on the rear arm, are much higher in magnitude. Figure 22 shows the deflection of the rear wheel hub when the motorbike faces curbs. Note that in this case the vertical deflection reaches values up to 0.6 mm.

Figure 23 shows a comparison between the vertical forces in the rear hinge in the rigid and flexible case. As expected, the forces in the flexible case are lower in absolute value, because part of the energy is used to deform the flexible component, which shows also a dissipative behaviour due to damping.

The overall behaviour of the motorbike in this case changes significantly due to flexibility, Fig.24 shows a comparison of the mass center quote of the motorbike in rigid and flexible case, the differences reach an absolute value of 10 mm. Moreover, when considering the flexible swingarm, an interesting behaviour appears.

If the simulation time is long enough, the virtual driver is no more able to control the vehicle, which starts to wave after some seconds. Figure 25 shows

the motorbike pose in both cases (flexible on the left and rigid on the right) at time  $t = 5.5$  s: the vehicle with a flexible swingarm comes into an unstable behaviour and is going to thumble. This behaviour, currently under investigation, is certainly due to a poor performance of the virtual driver and to a rough model of the tyres, but appears to be induced by swingarm flexibility.

Figure 22: Vertical and longitudinal displacement of rear hub when facing curbs.

Figure 23: Vertical forces in rear hinge, comparison between rigid and flexible case.

The main drawback of model with the flexible component is the computational cost due to the additional elastic degrees of freedom: the braking simulation experiment with a rigid swingarm takes 0.32 s of CPU time to simulate 7 s, on a normal laptop, the same model with a flexible swingarm takes about 10.4 seconds of CPU time; regarding the simulation of impacts, the rigid model takes 5 s while the flexible model takes 64 s for 3.5 s of simulated time. The DASSL integration algorithm has been used in all the simulations.

## 6 Conclusion and future work

In this paper, a Modelica multibody model of a motorcycle with a flexible swingarm is presented.

Figure 24: Mass center quote, comparison between rigid and flexible case.

Figure 25: Motorbikes with rigid (right) and flexible (left) swingarm at time  $t = 5.5$  s.

At first, a rigid model of the motorbike has been developed and validated with respect to a sudden braking transient.

Then, a general approach to the modelling of flexible bodies is presented, and the full procedure leading to the Modelica model is detailed.

The proposed modelling approach has been applied to the rear swingarm of the motorbike and a comparison between the rigid and the flexible case is presented, with reference to a sudden braking and a series of impacts with curbs as simulation scenarios. In particular, the simulation of the motorbike with a flexible swingarm showed an unstable behaviour in the case of subsequent impacts, largely due to a poor performance of the virtual driver, but undoubtedly induced by swingarm flexibility.

The developed approach to flexible multibody modelling will allow to easily include the description of bodies' flexibility in mechatronic systems, expanding the range of the dynamic analysis. In particular, the said unstable behaviour is currently under investigation, as well as another unstable behaviour (shimmy) occurring in racing bikes.

## 7 Acknowledgements

The authors would like to thank all people who supported this work: Dr. Marta Massera, for designing the frame and the swingarm, the Director of MUSP, prof. Michele Monno, and its staff for constant support, and RobbyMoto Engineering S.r.L., for valuable collaboration.

## Abstract

In this paper two semi-physical models of the semi-active dampers of the DLR robotic electric vehicle ROboMObil (ROMO) are described and their implementation in Modelica is presented. Besides the damper characteristics and hysteresis, the models additionally consider the gas force and cover the differences of the damper characteristics for compression and rebound. A procedure to identify the damper model parameters was implemented using the DLR Optimization library. The measurement data used for parameter identification was recorded during experiments on a damper test bench. The simulation results of the damper models are compared to the experiment data of the semi-active damper and the suitability of the damper models with respect to accuracy and real-time simulation is discussed.

*Keywords: semi-active damper; model identification, Bouc-Wen model, vehicle dynamics*

## 1 Introduction

When designing a suspension system there are generally two conflicting goals concerning satisfactory ride comfort and good road-holding. Using passive dampers this leads to a compromise since good ride comfort can be achieved by a rather soft damping whereas for good road-holding high damping is necessary. On the contrary, suspension systems with controlled semi-active dampers can mitigate this restriction by allowing the adaption of the damper force according to the current vehicle state. A comprehensive overview of control strategies for semi-active suspensions is given in [1, 2] or [3].

Semi-active dampers enable the continuous adaption of the damper force characteristics within a large

operation range dependent on a control input. The adaption inside the damper is realized by modifying the force generating physical effects of the damper. Therefore, semi-active dampers generally need little energy effort for control as only small forces are necessary to modify the damping force [2]. These two properties, low energy consumption and continuous adaption of the damper force, make the integration of semi-active dampers in vehicle suspensions attractive. In order to investigate the influence of all the aforementioned aspects in the context of an experimental electric vehicle, semi-active dampers are used in the ROMO.

The ROMO, see Figure 1, is an innovative robotic electric vehicle developed at the Robotics and Mechatronics Center of the German Aerospace Center (DLR). It is composed of four *Wheel Robots*, see [4], which integrate drivetrain, brakes, steering, and suspension.

Figure 1: The ROboMObil (ROMO) on the four post test rig

During the design process of semi-active suspen-

sions accurate purpose dependent models describing the behaviour of semi-active dampers are needed as shown e. g. in [5]. These models can then be used for full and quarter-car simulations as well as for estimator and controller design, see [6, 7] or [1].

Due to the ability to combine models from different physical domains like mechanics and/or electrics with control algorithms the object oriented modelling language Modelica is well suited for modelling and simulation of controlled semi-active dampers. Another advantage for modelling of electric vehicles like the ROMO is the possibility to reflect the hierarchical model structure which simplifies the handling and parameterization of large models.

The common component models for semi-active dampers can be separated into the following groups depending on the kind of modelling:

- Full physical models which include a mechanical and an electrical model of the damper as well as a hydraulical model of the fluid flow.
- Semi-physical models which also include the damper mechanics and electrics, but approximate the hydraulics by an empirical model.
- Black-box models – empirical models which do not include physical model information in any way.

A description of a physical damper model can be found in [8, 9] or [10]. A good overview of semi-physical models can be found in [11] or [12]. These two latter papers give an introduction to semi-active damper modelling and describe several semi-physical models like the Bingham model or the Bouc-Wen model. A look-up table based damper model is developed in [13]. The application of a black-box damper model is shown in [14]. There, the authors develop a nonlinear autoregressive exogenous (ARX) model and compare it to an extended Bouc-Wen model according to [11]. The results presented in the paper illustrate that both models reproduce the damper behaviour with a high accuracy while the nonlinear ARX model slightly outperforms the extended Bouc-Wen model.

This paper focuses on two semi-physical damper models – a modified generalized extended Bouc-Wen model and a model based on a 2-dim. look-up table with the damper velocity and the control input as inputs, further referred to as Force Map based damper model. In contrast to the extended Bouc-Wen model presented by [11] and used in [14] and [2], the extended Bouc-Wen model described in this paper dis-

tinguishes between compression and rebound (i. e. decompression) of the damper allowing different damper characteristics. This corresponds to the typical characteristics of semi-active dampers as used in vehicle suspension systems. Further, the dependency of the model parameters on the control input is modelled in a more general way, compared to [11], as the restriction imposed by the linear dependency of the parameters on the control input limits the performance of the extended Bouc-Wen model (see also [14]). Utilizing the implementation in Modelica, the model parameters are identified through a step by step optimization approach using the DLR Optimization library [15]. Hereby, the overall optimization task was split into several smaller subtasks each focusing on a subset of the overall model parameters and making use of particular experiment data specifically recorded for this optimization step. The advantage of this procedure is that the knowledge of the real damper structure and behaviour can be considered in the optimization algorithm and thus local minima finding can be avoided more easily during the optimization. Subsequently, the behaviour of the parameterized damper models is compared to the real damper behaviour and the feasibility of the damper models for real-time simulations is investigated.

The paper is structured as follows. In the next section the semi-active damper used in ROMO is presented. In section 3 the semi-active damper models are introduced and some implementation details are discussed whereas section 4 deals with the experimental setup and the identification approach. Subsequently, section 5 compares the simulated damper behaviour to the real damper behaviour.

## 2 The semi-active damper

In this work, a semi-active dual tube damper from the KW Automotive GmbH with one external controllable electromagnetic valve is used, see Figure 2. The adjustment of the damper force is realized by controlling the electric current flowing through the inductor of the electromagnetic valve. The induced magnetic field determines the position of the valve piston and consequently the oil flow through the valve. The flow direction of the oil through the external valve stays the same during both compression and rebound of the damper as the oil always flows from the rebound volume to the compensational volume.

Besides this electromagnetic valve there are further valves for compression and rebound, similarly to a conventional passive damper. They are placed at the

Figure 2: Semi-active dual tube damper with external continuously variable valve (coil spring was unmounted for experiments)

damper bottom and in the piston thus limiting the oil flow from the compression volume to the compensational volume and from the rebound volume to the compression volume, respectively.

Part of the compensational volume is filled with a pre-stressed gas to compensate the oil volume difference between pulled out damper and compressed damper caused by the piston rod. This gas volume can be regarded as an accumulator that generates a deflection dependent gas force. The gas force increases when compressing the damper and can therefore be considered as a preloaded spring in a damper model.

The electric current to control the damper is generated by a power electric unit which transforms the Pulse-Width Modulated (PWM) signal, further referred to as control input, from the Rapid Control Prototyping (RCP) hardware into the appropriate electric current. Figure 3 illustrates the speed-force map of the damper at the constant control inputs 10% (blue) and 50% (red) as recorded during experiments. The curves represent the raw damper force measurements and therefore reflect both the damper friction and the gas force influences.

The characteristic of the semi-active damper differs for compression (negative velocity) and rebound (positive velocity). This especially can be observed for larger control inputs as significantly higher rebound forces are generated, compared to compression ones, cf. Figure 3.

### 3 Semi-active damper models

The Force Map based damper model and the extended Bouc-Wen damper model were chosen for implementation in Modelica to investigate the achievable accuracy in reproducing the real damper behaviour and to evaluate their real-time feasibility.

In general, they both provide a good approximation of the highly non-linear behaviour of the semi-active

Figure 3: Speed-force map at control input 10% and 50%

dampers, whereas the computational effort is far less than that of physical models as they do not include a model of the damper hydraulics, but approximate it by an empirical model. Therefore, these semi-physical models can be solved more easily by a fixed step solver and are better suited for real-time simulation, state estimation and controller design.

The damper models are implemented as one-dimensional translational models and extend from the common translational interfaces of the Modelica Standard library.

#### 3.1 Generalized extended Bouc-Wen Model

An introduction to the Bouc-Wen hysteresis model can be found in [2]. The extended Bouc-Wen model as shown in Figure 4 is described in detail in [11]. There the authors started with a simpler model consisting of the linear damping element  $c_0$ , the linear spring  $k_0$  and the Bouc-Wen hysteresis model. To better predict the real damper behaviour, they extended this simple model by the elements  $c_1$  and  $k_1$  which reproduce the gas chamber damping and the roll-off at low velocities, respectively. To make the model applicable for semi-active dampers they further determined a subset of three parameters out of the ten parameters of the extended Bouc-Wen model which are then linearly adapted according to the current control input. This way, the extended Bouc-Wen model is able to cover the different characteristics of semi-active dampers de-

pending on the control input. Additionally, the control input was delayed by a first order low pass filter in order to better approximate the delayed real damper response towards changes in the control input due to the dynamic response of the electromagnetic valve and following the dynamic response of the damper hydraulics.

Figure 4: Mechanical model of the extended Bouc-Wen damper model (similar to [11])

Based on the model description in [11], we further generalized the extended Bouc-Wen model as described in the following.

First, the set of three originally suggested parameters depending on the control input is extended to seven parameters and the linear dependency on the control input is replaced by a predefined look-up table, see structure of the implemented Modelica model in Figure 5. This way, the restrictions on the dependency between control input and model parameters are far less than in [11] and the damper model should achieve a better prediction of the real damper. Next, the parameters of the extended Bouc-Wen model are additionally modelled as a function of the current damper velocity to account for the different characteristics of the damper for compression and rebound, cf. Figure 3.

Furthermore, the low pass filter which approximates the dynamic damper response for changes in the control input is modelled as a first order transfer function (block *firstOrder\_varT*) with an additional delay. The time constant as well as the delay time are considered to be functions of the instantaneous damper velocity (block *relSpeed*) and the sign of the derivative of the control input. This way, varying response times  $T_{comp,r}$ ,  $T_{comp,f}$ ,  $T_{rebound,r}$ ,  $T_{rebound,f}$  and delay times  $\tau_{comp,r}$ ,  $\tau_{comp,f}$ ,  $\tau_{rebound,r}$ ,  $\tau_{rebound,f}$  for compression and rebound as well as for rising and falling control inputs, indicated by the indices  $r$  and  $f$ , respectively, can be considered.

Utilizing the abovementioned extensions, the result-

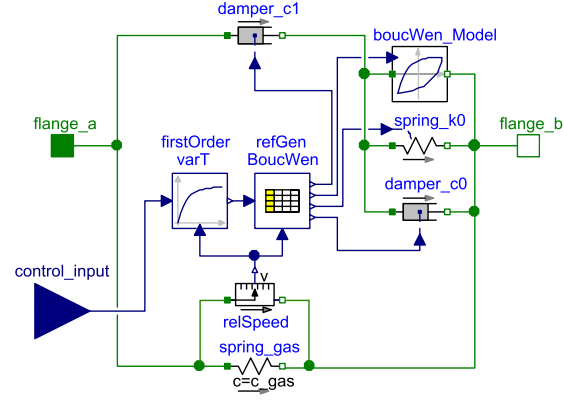

Figure 5: Generalized extended Bouc-Wen damper model

ing equations of the generalized extended Bouc-Wen model are given as

$$F_d = c_0(u, v_d)(\dot{x}_b - \dot{y}) + k_0(u, v_d)(x_b - y) + k_1((x_b - x_a) - x_0) + \alpha(u, v_d)z, \quad (1)$$

with

$$\dot{y} = \frac{1}{c_0(u, v_d) + c_1(u, v_d)} \left( \alpha(u, v_d)z + c_0(u, v_d)\dot{x}_b + c_1(u, v_d)\dot{x}_a + k_0(u, v_d)(x_b - y) \right) \quad (2)$$

and

$$\begin{aligned} \dot{z} = & -\gamma(u, v_d) |\dot{x}_b - \dot{y}| z |z|^{n-1} \\ & -\beta(u, v_d)(\dot{x}_b - \dot{y}) |z|^n \\ & +\delta(u, v_d)(\dot{x}_b - \dot{y}). \end{aligned} \quad (3)$$

The meaning of the displacements  $x_a$ ,  $x_b$ , which correspond to the motion of *flange\_a*, *flange\_b*, respectively, and the internal displacement  $y$  is clear from Figures 4 and 5. The variable  $z$  represents an internal state of the Bouc-Wen model and is often called hysteretic state. The spring stiffness  $k_1$  and the unstretched spring length  $x_0$  model the gas spring of the damper. Therefore, these parameters are considered invariant to changes of the control input  $u$  and the damper velocity  $v_d = \dot{x}_b - \dot{x}_a$ . The remaining parameters of the generalized extended Bouc-Wen model are  $k_0$ ,  $c_0$ ,  $\alpha$ ,  $\beta$ ,  $\gamma$ ,  $\delta$  and  $n$ . All these parameters are functions of the control input  $u$  and the damper velocity  $v_d$  except for the exponent  $n$ , which is empirically determined to be  $n = 2$  as in [2].

It is assumed that the dependency of the parameters on the damper velocity  $v_d$  can be approximated by a switching function which distinguishes between positive damper velocity for rebound and negative one for

compression. This means that for every set  $\theta_{eBW}$  of parameters two variants are generated – one for compression  $\theta_{eBW,comp}$  and one for rebound  $\theta_{eBW,rebound}$ . These sets are then stored in the look-up table mentioned above. To combine the two sets of parameters the following smooth switching algorithm is applied:

$$\theta_{eBW} = s \theta_{eBW,rebound} + (1 - s) \theta_{eBW,comp}, \quad (4)$$

with the switching signal  $s$  which is given by the following sigmoid function:

$$s = 0.5 \tanh\left(\frac{v_d}{v_{eps}}\right) + 0.5. \quad (5)$$

This function generates a smooth output that changes from zero to one in a small region around zero damper velocities  $v_d$ . The size of this region is determined by  $v_{eps}$ . Although other switching signals like  $s = \text{sign}(v_d)$  would be possible, such a smooth switching signal is better suitable for a real-time simulations as no events occur. The function calculating the time constant of the first order transfer function and the delay time from the current damper velocity  $v_d$  and control input derivative is implemented using a similar switching algorithm as the one described in equations (4) and (5).

### 3.2 Force Map based model

Figure 6 shows the Force Map based damper model implemented in Modelica. The control demand applied to the damper model is again (as in section 3.1) modelled by a transfer function and an additional delay with time constants and delay times dependent on the damper velocity  $v_d$  and the control input derivative. The main component of this damper model is a *lookUpTable*, which takes the current damper velocity and the delayed control input as inputs and computes a force. Additionally, a model of the gas spring is included to improve the damper model for large deflections. The overall damper force is therefore given by:

$$F_d = F_{lookup} + F_{gas}, \quad (6)$$

with the output of the look-up table  $F_{lookup}$  and the gas force  $F_{gas}$ .

The implemented model is similar to the one developed in [13]. The main differences between these two models are the negligence of the damper housing stiffness which is very high and therefore causes stability problems during real-time simulations.

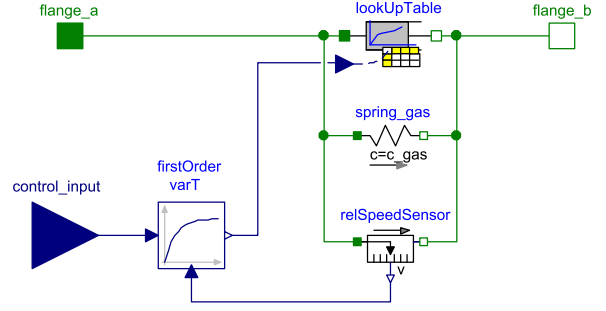

Figure 6: Force Map based damper model

## 4 Parameter identification

The parameter identification of the two semi-active damper models introduced in section 3.1 and 3.2 is a challenging task because both models are highly non-linear and additionally the number of parameters to be determined is large. The arising optimization problem is non-convex and a lot of effort is necessary in order to avoid local minima evaluations. In this work, the optimization problem at hand is split into several subproblems as suggested in [13] and [2], estimating successively subsets  $\theta_j$  of the overall parameter vector  $\theta$ .

The parameter subsets  $\theta_j$  are chosen from experience and technical understanding of the damper in such a way that specific experiments focusing on identification of these parameters can be performed. The suboptimization problems are arranged in a chronological order and the estimated parameter subsets resulting from previous steps are inserted in the current optimization run. Although some of these suboptimization problems are non-convex as well, local minima can be avoided more easily by a careful choice of the initial values of the parameter subsets. This is achievable because the optimization problem is smaller compared to the overall optimization problem.

Throughout all suboptimizations, a cost function

$$J = \frac{\frac{1}{N} \sum_{i=1}^N \left( F_{d,m} - F_{d,s}(\theta_j) \right)^2}{\frac{1}{N} \sum_{i=1}^N \left( F_{d,m} - \left( \frac{1}{T} \sum_{j=1}^N F_{d,m} \right) \right)^2} \quad (7)$$

is used.

This cost function, which is also used by [14], represents the error-to-signal-ratio of the simulated damper force. Here, the number of the measured data samples is denoted by  $N$ . The measured damper force is represented by  $F_{d,m}$  and the simulated damper force by  $F_{d,s}$ .

The suboptimization problems can now be stated by

$$\text{find } \underset{\theta_j}{\text{argmin}}(J) \text{ subject to } \theta_{j,\min} < \theta_j < \theta_{j,\max}, \quad (8)$$

with  $\theta_{j,\max}$  and  $\theta_{j,\min}$  restricting the maximum and minimum parameter values.

The optimization is done in Modelica/Dymola using the model optimization functions of the DLR Optimization library [15]. From the various optimization algorithms available in this library the *Simplex method* was chosen in this work as the algorithm proved satisfactory and fast convergence during preliminary investigations. A default cost function value larger than the initial cost function value was defined in the optimization setup to handle simulation runs with the generalized extended Bouc-Wen damper model which became unstable for certain parameter sets.

#### 4.1 Experimental Setup

The experiments were performed on a Röhrig damper test rig which is shown in Figure 7.

Figure 7: Experimental set-up

This test rig is equipped with a linear electric motor and therefore able to generate various damper excitations like sine sweeps or constant velocity periods. The measurement data was recorded using a Microautobox 2 from dSpace. The sample period of the RCP

system was set to  $T_s = 1$  ms. The measured signals are damper force, displacement and acceleration. These signals are recorded together with the control input and are pre-filtered by a low-pass FIR filter.

#### 4.2 Step by Step optimization approach

The size of the overall parameter vector  $\theta_{eBW}$  of the generalized extended Bouc-Wen model depends on the number of nodes in the look-up table storing the control input dependent parameters as described in section 3.1. Each control input segment is represented by one row in this look-up table. The elements of the parameter vector  $\theta_{eBW}$  are:

$$\theta_{eBW} = (k_0, x_0, \theta_{eBW,i,2}, \dots, \theta_{eBW,i,m+1}, T_{i,r}, T_{i,f}, \tau_{i,r}, \tau_{i,f})^T, \quad (9)$$

with

$$\theta_{eBW,i,j} = (c_{0,i,j}, k_{0,i,j}, c_{1,i,j}, \alpha_{i,j}, \beta_{i,j}, \gamma_{i,j}, \delta_{i,j})^T. \quad (10)$$

Here,  $i$  stays for *comp* or *rebound*,  $j = 2, \dots, m+1$  and  $m$  is equal to the number of control input segments. This parameter vector is split into the following  $m+2$  subsets.

- Gas force identification

$$\theta_{eBW,1} = (k_0, x_0)^T. \quad (11)$$

Experiment: Constant, very small velocity excitation for compression and rebound at constant minimum control input  $u_{\min}$ .

- Bouc-Wen parameter identification at constant control input  $u_1$ :

$$\theta_{eBW,j} = (\theta_{eBW,\text{comp},j}, \theta_{eBW,\text{rebound},j})^T. \quad (12)$$

Experiment: Sine excitation of the damper with an amplitude of 25 mm and a frequency of 0.8 Hz.

- Time constant and delay estimation

$$\theta_{eBW,m+2} = (T_{\text{comp},r}, T_{\text{comp},f}, T_{\text{rebound},r}, T_{\text{rebound},f}, \tau_{\text{comp},r}, \tau_{\text{comp},f}, \tau_{\text{rebound},r}, \tau_{\text{rebound},f})^T. \quad (13)$$

Experiment: Saw tooth excitation of the damper with an amplitude of 25 mm and a constant damper velocity with an absolute value of  $0.15 \text{ ms}^{-1}$  for compression and rebound.

As an example, Figure 8 shows the virtual test rig for the optimization of the Bouc-Wen parameters at control input  $u_1$ . Similar virtual test rigs are employed to optimize the other parameter subsets. Therefore, the measurements have to be replaced by the corresponding measurement data, e. g. with a different control input.

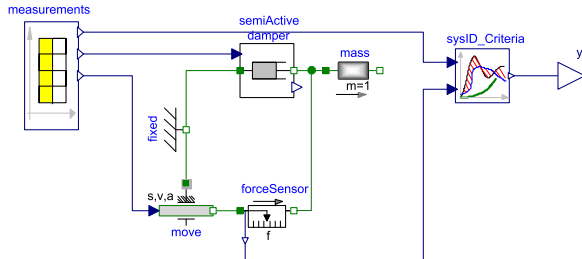

Figure 8: Virtual test rig for optimization

On the left-hand side of the model the measurement data is read by a *CombiTimeTable* called *measurements*, on the right-hand side the cost function is calculated by the *sysID\_Criteria* block and in the middle the damper model *semi-active damper* is excited by a *move* element supplied with the measured displacement and derived velocity and acceleration.

The estimated gas force of step one is inserted as known value in the damper models for the following optimization steps and, further, the estimated parameters  $\theta_{eBW,j}$  (with  $j = 2, \dots, m+1$ ) of the previous step are used successively as initial values for the parameter vector  $\theta_{eBW,j+1}$  of the following step. The initial values of the extended Bouc-Wen model for the first step are taken from [12] and the corresponding minimum parameter values  $\theta_{j,min}$  and maximum parameter values  $\theta_{j,max}$  are defined by scaling the initial parameter values.

The optimization procedure for the Force Map based damper model is very similar to the one of the extended Bouc-Wen model. The first step gas force estimation and the last step time constant estimation are the same. The steps in between are used to estimate the values of the *lookUpTable*, which takes the damper velocity and the control input as inputs and calculates a force as output. As the control input is constant during these steps, the values are again determined row by row.

### 4.3 Optimization results

The resulting cost function values for both damper models are shown in Table 1. The models reproduce the real damper behavior with almost the same accu-

racy. For a control input of 10% the Force Map model and the extended Bouc-Wen model achieve the same accuracy. For a control input of 50% the extended Bouc-Wen model achieves slightly better values than the Force Map model.

Table 1: Optimal cost function values of the damper models

Damper model	Control input	
	10%	50%
Extended Bouc-Wen	0.097	0.090
Force Map	0.095	0.117

The corresponding force over time, force over displacement and force over velocity diagrams for 10% and 50% control input are illustrated in the figures 9 and 10. The slight accuracy difference indicated by the cost function value for 50% control input is most obvious in the force over velocity diagram (Figure 10 below), mainly in the small velocity region.

In Figures 11 and 12 the results of the time constant and time delay identification for control input steps during rebound and compression are shown. The damper velocity was kept constant for rebound and compression to isolate the damper response for control input steps only. The modelled time behavior of the damper consisting of a first order transfer function and a delay with different time constants and delay times for rebound and compression as well as dependent on the direction of the control input change as described in section 3.1, is able to reproduce the damper behaviour very well. From Figures 11 and 12 it can further be seen that the delay is almost as large as the time constant of the transfer function and therefore the delay cannot be neglected by the damper model.

### 4.4 Real-time suitability

The parametrized damper models were simulated by a fourth-order Runge-Kutta solver with a fixed step size of  $T_s = 1$  ms to analyse their feasibility for real-time simulations, as this solver is used to run the real-time model of the ROMO. The Force Map based damper model showed good results for this solver, while the generalized extended Bouc-Wen model became unstable for the optimized parameters.

Figure 9: Comparison of damper models to damper measurements at 10% control input (above: force over time; middle: force over position; below: force over velocity)

## 5 Conclusion

In this paper two semi-physical damper models are presented and their accuracy in reproducing the real damper behavior is compared. Both models achieve a high accuracy in the considered velocity and frequency range. The generalized extended Bouc-Wen model gives more accurate results especially for higher control input.

On the other hand, the Force Map based damper model proved a better suitability for real-time simulation due to its more robust stability properties depending on the chosen solver and step-size and its simpler structure.

In the future, the velocity and frequency range of the damper models have to be extended towards higher values to improve the damper models for larger operation ranges. Further, the influence of stiction and sliding friction on the damper model accuracy for small

Figure 10: Comparison of damper models to damper measurements at 50% control input (above: force over time; middle: force over position; below: force over velocity)

control inputs and small velocities have to be investigated as well.

## Acknowledgement

The authors would like to thank Dr. Johann Bals and Mr. Jonathan Brembeck for their support and Mr. Uwe Bleck for his expertise in questions of applied vehicle dynamics. A special thank of the authors goes to Dr. Andreas Pfeiffer for his great support in application questions concerning the DLR Optimization library. The authors further would like to thank the KW Automotive GmbH for providing the semi-active damper and the damper test rig.

# The Modelica *HouseModels* Library: Presentation and Evaluation of a Room Model with the ASHRAE Standard 140

Ana Constantin Rita Streblow Dirk Müller

RWTH Aachen University, Institute for Energy Efficient Buildings and Indoor Climate  
Mathieustr. 10, 52074 Aachen

## Abstract

As part of its contribution to IEA Annex 60, the Institute for Energy Efficient Buildings and Indoor Climate of RWTH Aachen University will make its Modelica *HouseModels* library available. The scope of this paper is to provide information about the library. The first part presents the library and its functionality. In the second part a room model is evaluated by using Case 600 from the test suite provided by the American Society of Heating, Refrigerating and Air-Conditioning Engineers (ASHRAE) in the standard 140.

*Keywords:* *HouseModels* library, IEA Annex 60, ANSI/ASHRAE Standard 140, building performance simulation

## 1 Introduction

The Institute for Energy Efficient Buildings and Indoor Climate of RWTH Aachen University aims through its research to reduce the energy consumption of buildings and increase indoor air quality, while focusing on energy generation, storage, distribution and delivery to rooms, buildings or city districts. Over the years several libraries have been developed for the dynamical simulation of building energy systems [1].

On a simulation level, modeling the thermal behavior of the construction body and the building envelope has to mediate the following trade-off: CPU(central processing unit)-time and detail. The building models serve on a basic level as an energy consumer. However through accurate modeling of heat transfer inside the building it is possible to assess the thermal comfort, while taking into account more subtle effects like the storage of energy into the thermal mass of the building. As part of its contribution to IEA Annex 60 [2] the institute will make its Modelica *HouseModels* library available.

The *HouseModels* library aims to provide standard

models for one family dwellings (stand alone house), single apartments and multi-family dwellings consisting of several apartments. The particularity of this library lies in providing ready to use models for the dynamic simulation of building energy systems, while allowing for a degree of flexibility in adapting or extending these models to ones needs.

A library with models for standard houses as such does not yet exist. While at the moment the standard house models are tailor-made for the German market, it is possible to adapt them to other markets.

For the building models we used components from our *Buildings* library [1]. When setting up detailed house models, we follow an approach of building each room individually and of having each room component visible on the room model level. This approach was formed with time by dealing with project partners in our research activities and with students in our teaching activities. We analyzed how easy it is to understand the model and how quickly one can start working with it. As a consequence the graphical description of a model can quickly get cluttered, so we try to keep our detailed house models as simple as possible. An advantage of simple models with few equations is that, when set up correctly, they can lead to short CPU-times for simulations. In order to make sure that these models are correct they need to be evaluated. We choose the ANSI/ASHRAE Standard 140 [3] for evaluating or models.

Several Modelica libraries for building components already exist, some of them free [4] and [5]. While the *Buildings* library is already validated [6], we chose to use our own components when building the house models in order to maintain consistency between our libraries and because our models are simpler than the ones from the *Buildings* library. We need them as simple as possible when for example doing whole year simulations for a set up consisting of a building and its heating system, especially when the focus lies on the components in each room. For a direct comparison

between our room model and the one from the *Buildings* library please refer to [4] and section 2.2 in this paper, which in order to allow for an easy comparison are similarly structured.

The first part of the paper presents the *HouseModels* library, while the second one presents the first steps in the ongoing work of evaluating our models with the ASHRAE Standard 140: the results for the case 600.

The library was developed using the commercial simulation environment Dymola [7].

## 2 The *HouseModels* library

When developing the *HouseModels* library we followed several goals:

- develop standard models
- model only the necessary physical processes
- build a model so that changing the parameters is easy, quick and will not lead to hidden mistakes
- have an easy to use graphical interface
- ensure a degree of flexibility for expanding or building new models

We call these house models *standard* for the following reasons:

- the floor layouts were made based on existing buildings, by analyzing data provided by the German Federal Statistical Office and by consulting with experts
- for modeling realistical wall structures building catalogues as well as experts were consulted
- the physical properties of the materials for the wall layers were chosen to satisfy the insulation requirements of current and past German energy saving ordinances (e.g. [8])

### 2.1 Library structure

Figure 1 presents the structure of the library. The package *Rooms* contains room models for one (OFD) and multi-family dwellings (MFD).

The multi-family dwelling is based on an existing building consisting of several identical apartments which is part of a larger national research project [9]. The dimensions and layout of the rooms are fixed, with

Figure 1: Structure of *HouseModels* library

an apartment having a living area of 70 m<sup>2</sup> and consisting of a living room, two bedrooms, a kitchen and a bathroom.

The one family dwelling isn't based on an existing building, but on a virtual two storey building with ten rooms and a saddle roof, which is typical for German houses. The living area is 150 m<sup>2</sup>. A core of six room types was developed to model the different rooms in the house: room types with two outer walls and room types with one outer wall. Some inner walls can face just one room, while others can face two rooms. Rooms on the ground floor are connected to the ground, while rooms on the upper floor have a saddle roof. The layout of the two floors is the same. The dimensions of the room are not fixed on a room level and are set up at floor level.

The package *House* contains the set up house models, where the room models are connected together. The name *OFD\_MiddleInnerLoadWall* denotes the fact that the standard house has a middle load bearing wall. Other positions of the load bearing inner wall are possible, but not included in the library. Walls are connected together and they form a room. Multiple rooms are connected together and they form a storey for the one family dwelling and an apartment for the multi-family dwelling. For the multi-family dwelling it is possible to model several storeys with apartments on top of each other, as well as several wings with apartments next to each other. Storeys are connected together to form a whole house. All connections between the connectors of the models are explicit.

For each standard house type there are packages for the building envelope (*Building*), for the energy system (*EnergySystem*) and for the building as a whole (*BuildingAndEnergySystem*). Currently work is be-

ing done on the models for the energy supply systems consisting of pump, heat generator, pipes, thermostatic valves and radiators. These models are being developed starting from more detailed models to be used as a teaching tool for a course on simulation of building energy systems. They will be made available later on as part of our contribution to the IEA Annex 60.

The package *Examples* contains exemplary simulation setups for a room, an apartment and a one family dwelling. They can be used to learn how to set up a simulation for these models (e.g. assumption for boundary conditions for a single room) and to compare the different CPU-times for simulations using the models.

## 2.2 Room model

In a room model the following physical processes are considered:

- transient heat conduction through walls; each wall consists of several layers with different physical properties; further discretization of each layer is possible
- steady-state heat conduction through glazing systems; transmission of short wave radiation through the window depends on a constant coefficient; transmitted radiation is considered together with the radiation from room facing elements
- heat convection at outside facing surfaces either with a constant coefficient, depending on wind speed, or depending on wind speed and surface abrasiveness
- heat convection at inside facing surfaces depends on the wall orientation and the temperature difference between the room air and the wall surface
- radiation exchange between room facing elements
- temperature balance equations for the room air volume; per room only one air node is considered; humidity is not considered in the air node

The incident solar radiation on tilted surfaces is calculated using a isotropic sky model [10].

All outer walls are whole walls connected to the room air and the ambient, while inner walls are half walls, each half belonging to one of the rooms which share the wall. Airflow among rooms is not explicitly considered.

## 2.3 Model parameterization

The room model is realized by aggregating together all the components in a model, parameterizing on a room level and referencing the parameter on the component level. In this way the number of parameters is reduced, e.g. for a simple rectangular room only three parameters are needed for the dimensions of all the walls: height, length, width. On a floor level this parameterization can further be optimized, as rooms have common walls.

However not the geometrical measurements are the most problematic when parameterizing a room, but the wall types, meaning their layer structure and the physical properties of each layer. We use records for parameterizing a wall. A record contains information about the number of layers, the thickness of the layer, as well as density, thermal capacity and conductivity of each layer material together with the emissivity of the room facing layer. However setting or changing the type of each wall in each room in a house can be challenging and can lead to errors. Because we aim to build standard house models, we want to parameterize a standard house with minimal but relevant input and not have to specify each wall individually. We chose to parameterize according to the following criteria:

- thermal mass class: heavy, middle and light
- energy saving ordinance: along with the already mentioned ordinance form 2009, older ordinances from 2002, 1995 and 1984 are considered

By specifying these two parameters, all wall, window and door types in a house are automatically set correctly.

In listing 1 an example is given of how to set up the parameter for the floor type depending on the set energy saving ordinance. As floor slabs are made of concrete for stability reasons, there is no difference between the floor types for houses with different thermal mass. As this type of coding is meant to help and not confuse a user, all these parameters are protected. The infiltration rate for a house is protected as well and depends on the energy saving ordinance. The *DataBase* library referenced in the listing is a library for records. The packages which are relevant for the *HouseModels* as well as any other relevant models, e.g. walls, windows, will also be made available.

Furthermore for a multi-family dwelling, for each apartment, the types for floor and ceiling are automatically set if the apartment is situated on the ground, last or an arbitrary upper floor.

## 2.4 Using and extending the library

We wanted to make the library easy to use and extend by future users and developers. To this purpose we put extra effort in creating easy to understand icons and graphical interfaces for parameter input.

Figure 2 shows the needed parameters for a room type with two outer walls. The room views integrated in the parameter window help the user understand which are the width and the length of the room, where each wall type is situated and what possibilities regarding windows and doors exist for the outer walls. For each outer wall both a door and a window are possible. By checking the box for a window, element input fields for parameters are enabled. In the given example the outer wall OW1 has a window and the outer wall OW2 has a door. The already mentioned parameters for thermal mass and energy saving ordinances are visible at the top level. Other necessary parameters include the solar absorptance coefficient of the walls and the heat convection model at outside facing surfaces.

However once the parameter window is closed, the information about the geometry of the room is no longer available. Because users might want to rotate or mirror a room to build up a whole floor, we wanted to transfer the information about the position of the walls in the room, the meaning of the parameters width and length as well as the existence of windows on the icon level.

Figure 3 shows the icon for the parameterisation from figure 2. The text for the connectors was added in post-processing. However the connectors themselves have unique, easy to understand names. The information about the width and the length of the room is fixed. The thickness of the pictures for the walls indicates if

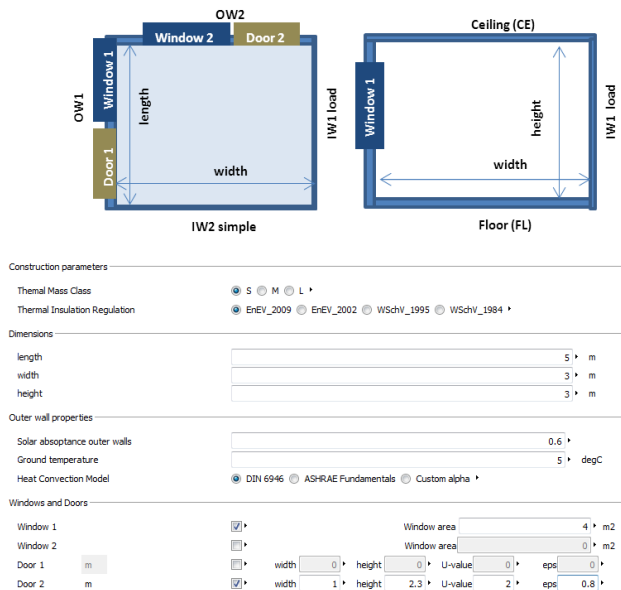

Figure 2: Parameter window for a room type

it is an inner or an outer wall. The square with the name *Win1* indicates the presence of a window on that wall, and the number *1* indicates that this is wall 1. The square is only visible if the window has been selected for the wall. In this way it is easy to combine the information given by the icon to the one which needs to be inputted in the parameter window.

Figure 3: Icon for a room model

The set of room types developed for the one family dwelling can, if necessary, be parameterized differently than the standard model or extended in order to build up specific house models. New sets of wall, win-

dow and door types can be developed, e.g. for older, not renovated buildings, and incorporated in the existing structure.

With the exception of the integration of images in the parameter GUI, which is done by using a Dymola specific annotation, all other annotations are independent of the used simulation environment. Also the SI-units package from the Modelica Standard Library is sufficient for using the library.

We use this library in our teaching activities as well, as it is representative of our research activities and quite complex. With the help of a custom made tutorial we help students better understand working with Modelica from a building systems performance simulation point of view. The library is planned to be made available via a dedicated website in summer 2014.

### 3 Evaluation with Case 600 of ASHRAE Standard 140

The ASHRAE Standard 140 is widely used for the evaluation of building performance simulation software especially in the English speaking community. The test suite offers a variety of tests used for validation (base cases) and for evaluation and improvement of software tools (in-depth cases). In this paper we will present the results from using a room model build with our components in the simulation setup for case 600.

Case 600 is a case which tests a low mass building without shading. The building is a rectangular room with all surfaces facing to the outside, decoupled from the ground, with a height of 2.7 m, a length of 6 m and a width of 8 m. The south facing wall has a window area of 12 m<sup>2</sup>. Detailed information about the test is provided in [3]. Once the simulation results are calculated, the way to test them is by comparison with the simulation results from other software tools, which are provided in the standard. In the following subsections the results obtained with our room model are labeled *HouseModels Lib.*

In this paper we will presents results from evaluating the solar radiation model as well as the heating and cooling behavior of the room.

#### 3.1 Solar radiation model

The case offers a frame for evaluating the calculation of the solar radiation on a tilted surface, by providing results for solar radiation profiles for clear and cloudy days, for the south and west facing walls.

Figure 4 presents the solar radiation on the south side on a cloudy day, while figure 5 presents the results for a clear day. The profiles are similar to the ones obtained with the other programs, never going outside the maximal and minimal specified ranges.

Figure 4: Comparison of hourly incident solar radiation for a cloudy day (March 5)

Figure 5: Comparison of hourly incident solar radiation for a cloudy day (July 27)

#### 3.2 Heating and Cooling behavior

For evaluating the heating and the cooling behavior of the room, annual heating and cooling loads and annual hourly peaks as well as profiles for exemplary days are calculated.

When considering the whole year, figure 6 presents a comparison of the heating and cooling loads for the whole year. The results for the annual heating load 5.081 MWh and cooling load 6.636 MWh are within the limits obtained with the other simulation tools.

Figure 6: Comparison of annual heating and cooling loads

A more detailed look at the annual hourly heating and cooling peak loads (absolute value as well as day and hour when it occurs) is presented in tables 1 and 2. The peak heating load of 4.132 kW occurring on the 4<sup>th</sup> Jan and the peak cooling load of 6.2621 kW occurring on the 16<sup>th</sup> Oct are similar to the results from the other programs: they are within the given limits and there is at least one software which gives the same time of occurrence. The occurrence of the maximum cooling load on 16<sup>th</sup> Oct is explained by the concurrence of a high ambient temperature of 22.2°C and a high incident solar radiation on the south side of 874  $\frac{W}{m^2}$ .

Table 1: Annual hourly integrated peak heating loads

Code Name	kW	Date	Hour
ESP	3.437	4 JAN	5
BLAST	3.940	4 JAN	5
DOE2	4.045	4 JAN	5
SRES/SUN	4.258	4 JAN	2
TRNSYS	3.931	4 JAN	6
TASE	4.354	4 JAN	2
HouseModels Lib.	4.132	4 JAN	2

Table 2: Annual hourly integrated peak cooling loads

Code Name	kW	Date	Hour
ESP	6.149	17 OCT	13
BLAST	5.965	16 OCT	14
DOE2	6.656	16 OCT	13
SRES/SUN	6.827	16 OCT	14
TRNSYS	6.486	16 OCT	14
TASE	6.812	17 OCT	13
HouseModels Lib.	6.261	16 OCT	13

Finally the test requires a comparison of the heating and cooling load profiles for the day with the highest heating load. Positive loads are heating loads, while negative loads are cooling loads. As shown in figure 7 the results obtained with our room model are similar to the ones from the other simulation tools.

Figure 7: Comparison of hourly heating and cooling load profiles for Jan 4

## 4 Conclusion

In this paper we present our *HouseModels* library, which will be made available free of charge in summer 2014, as part of our contribution to the IEA Annex 60. The library contains complete standard house models for one and multi-family dwellings. The multi-family dwelling also contains a model for a single apartment. For each house type the models can be easily parameterized for different thermal masses and energy saving ordinances. A variation of the geometrical measure-

ments is possible for the one family dwelling. This type of variations are useful when testing energy concepts and control strategies, as a robust system has to be able to adapt to different types of buildings.

Our motivation for creating this library is to bridge the gap between developers and users of Modelica for dynamic building system simulations. The models are easy to understand and use. Extra effort has been made to enrich the parameter window and to make the icons dynamic in regard to the chosen parameters. In order not to confuse beginners certain parameters have been set as protected and the parameterization of a room model can be done by specifying only a handful of parameters. The library is a useful tool for teaching, as students can learn to use Modelica with a focus on building systems while at the same time learning a few programming tricks.

The set of room types developed for the one family dwelling can, if necessary, be parameterized differently than the standard model or extended in order to build up specific house models.

As we try to keep the models as simple as possible and as detailed as needed in order to have good CPU-times for the simulations, a validation of the room models is currently on the way. In this paper we present first results obtained with case 600 of the ASHARE Standard 140. For all the required outputs our room model produced results within the minimum and maximum specified ranges. We plan on further evaluating the models with the whole suite of tests and improving the models if necessary.

## Abstract

This paper presents a Modelica library for electrical grid systems for low-voltage distribution grids and in-building grids. The library is based on previous work, in which a library was presented to simulate fully balanced three-phase low-voltage distribution grids [1]. This library is extended to simulate three-phase unbalanced low-voltage distribution grids as part of the IDEAS library [2]. The library also allows to simulate in-building AC and DC grids. The AC grids can be single-phase or three-phase (un)balanced grids. Electrical grids may connect many different energy systems (loads and generation units), different grids and/or buildings within districts. The library allows to assess the grid impact of these systems on different grid types. Control or optimization strategies can use grid variables, such as voltages and power exchanges.

*Keywords:* Electrical grid; AC grid; DC grid; Power flow analysis; Modelica

## 1 Introduction

Climate and energy goals are set, i.e. the European 20/20/20 targets [3]. One of these targets is an improvement in the EU's energy efficiency and the integration of renewable energy resources (RES) in the power production. Also, energy goals and benchmarks at the level of individual buildings are stated in the European Directive 2010/31/EU [4]. It is stated that by 2020 all new buildings need to be nearly zero-energy buildings (nZEB). nZEBs target a high penetration of RES, such as photovoltaic (PV) systems, and a high energy efficiency in the built environment.

This integration of RES and energy-efficient technologies in buildings may result in an increased elec-

trification. Also different domains, such as the electrical and thermal domain, tend to become more integrated. This requires new approaches to analyze these integrated systems [5], such as taking into account the limitations of an electrical grid or using grid variables as control inputs in building design simulations. This may lead to a more effective analysis and better control of the energy system under consideration.

### 1.1 Electricity grids

#### 1.1.1 Radial versus meshed grids

In the electrical power system, two types of electricity grids exist, namely distribution and transmission grids [6]. Distribution grids (low to medium voltage level) often differ fundamentally from transmission grids (high voltage level). Transmission grids are mostly meshed grids, whereas distribution grids are mostly radially. This means there is only one point of common coupling (PCC), which reduces the reliability of the distribution network. In case of a fault, all loads behind the fault will be switched off. Second, the R/X (resistance/reactance) ratio increases when the voltage level decreases. Thus, low voltage residential distribution grids are highly resistive.

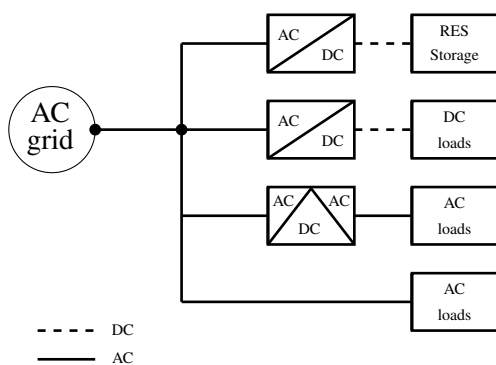

Electricity grids in buildings are similar to low-voltage distribution grids. As buildings are connected to the grid at one point, these grids are also radial. Loads (or buildings) can be single-phase or three-phase connected to the grid. Electrical grids in buildings can be a combination of different single and three-phase cables which connect the loads (see Fig. 1).

#### 1.1.2 AC versus DC in-building grids

The current AC distribution grid and AC in-building grids are traditionally designed to feed AC and DC

**Figure 1:** Comparison of low-voltage distribution grids (left) and in-building grids (right).

**Figure 2:** A traditional AC in-building grid with distributed converters (e.g. in appliances).

**Figure 3:** A possible hybrid AC-DC grid with a central bidirectional converter (AC/DC).

loads (e.g. household appliances) with distributed converters, e.g. rectifier in an appliance (see Fig. 2). Since almost all electric loads are equipped with power electronic converters, the interest in DC grids increases. It may lead to efficiency and economic advantages by reducing the losses [7]. Also, the harmonic distortion can be significantly reduced, which saves energy and improves the lifetime of equipment [8]. And a central AC/DC connection with the distribution grid can help to solve the three-phase balancing problem. Fig. 3 shows a possible lay-out of a hybrid AC/DC electrical grid for buildings. This grid includes e.g. a central AC/DC converter, a central DC/DC converter for the DER, storage units, EVs, etc. and DC/DC converters for loads on different DC voltages.

## 1.2 Electricity grid impact

Energy efficiency can be achieved by a further electrification through new, more efficient technologies such as heat pumps and electric vehicles (EVs) [9]. However, from the electricity grid point of view, these new

technologies have a twofold grid impact.

First, the power consumption will increase. For instance, when full EVs are charged only at home, the additional power consumption of about 2,350 to 3,750 kWh doubles the average Flemish household's power consumption. On the other hand, local RES will introduce bidirectional power flows due to a certain non-simultaneity with the local demand [10].

Second, the increased power consumption and the intermittent production character of RES and its potential non-simultaneity with the local power demand have an impact on the low-voltage electricity grid [10]: both the distribution and in-building grid. The injection of electricity and the increased power consumption may lead to peak loads and higher resistive losses. As LV grids are mainly resistive, voltage deviations and phase unbalance occur due to the active power flows [2, 10, 11]. To minimize the grid impact, a proper synchronization of consumption and production of electricity and heat is needed through demand side management (DSM), electrical and thermal sto-

range and minimizing the power consumption [9].

Taking into account the limitations of an electrical grid or using grid variables as control inputs in building design simulations, may lead to a more effective analysis and better control of the energy system under consideration.

### 1.3 Scope of paper

To investigate the impact of energy systems on the electrical distribution grid or in-building grid, a library is developed to simulate both single and three-phase unbalanced AC radial grids and DC electrical grids. For AC grid analyses, a quasi-stationary model is implemented, assuming the frequency is fixed (e.g. 50 Hz). This allows to represent the waveforms by its amplitude and phase shift. Therefore, dynamic transient are not included.

In previous work, the first version of this library was presented [1]. This library consisted of models for the modeling of balanced three-phase low-voltage distribution grids, which can be represented by an equivalent single-phase grid. This paper discusses the recent additions: the unbalanced three-phase low-voltage grids and DC grids.

First, the basics on power flow analyses is given in Section 2. Section 3 and 4 describe the physical and the model description in Modelica. To conclude, a comparative model validation is performed.

## 2 Power flow analysis

A power flow analysis is performed to obtain the voltage and current information in each node and line of the electrical grid, based on the Laws of Kirchhoff:

**Conservation of electric charge** The sum of currents flowing into a node is equal to the sum of currents flowing out of a node.

**Conservation of energy** The sum of the voltage drops in any closed circuit is zero.

The voltage drop  $\Delta v$  in a line  $k$  between nodes  $n$  and  $n + 1$  is defined as:

$$\Delta v_k(t) = v^n(t) - v^{n+1}(t) = Z_k i_k(t), \quad (1)$$

with  $Z_k$  the impedance of the line and  $i_k$  the line current. When the nodal currents, line currents and nodal voltages are known, the apparent power in one phase  $S_f$  can be calculated.  $S$  consists of active power  $P$  and reactive power  $Q$ :

$$S_f(t) = P_f(t) + jQ_f(t) = v_f i_f^*, \quad (2)$$

with a non-linear relation between  $S_f$ ,  $v_f$  the phase voltage and  $i_f^*$ , the complex conjugate of the total phase current  $i_f$ . The total apparent power is calculated as  $S(t) = \sum S_f$ . For DC grids:  $Q = 0$ .

The joule losses  $P_J$  in a grid are the sum of the losses in all phases and neutral (or negative) conductor. The joule losses in a line  $k$  are calculated as follows:

$$P_{J,k} = R_k |i_k|^2, \quad (3)$$

with  $R_k$  the resistance of a line  $k$ . Note that also the reactive current is responsible for a part of  $P_J$ .

The non-linear system requires numerical methods to obtain a solution. Several methods are available to solve a power flow analysis, such as direct and iterative methods. The *backward-forward sweep* is an example of an iterative method, which is well suited for radial grids. This method is illustrated in Appendix A. In Dymola, the DASSL solver [12] is used to solve the power flow analysis.

In [13], a three-phase unbalanced power flow analysis is implemented in MATLAB. This model uses the backward-forward sweep technique. The models in the developed Modelica library will be validated with this MATLAB model. Other available Modelica libraries regarding electrical systems are e.g. the SPOT library [14] and Electric Power Library [15] which allow both steady-state and transient simulations.

The library in this paper allows to do a quasi-stationary analysis of electrical grids. This allows to represent the waveforms by its amplitude and phase shift. Dynamic transient are not included.

## 3 Physical model description

### 3.1 Grid topology representation

Traditionally, radial grids are represented by an incidence matrix (or connection matrix)  $\mathbf{T}$ . Eq. (4) gives an example of an incidence matrix of a grid in which consecutive nodes are connected.

$$\mathbf{T} = \begin{bmatrix} -1 & 0 & 0 & \cdots & 0 & 0 \\ 1 & -1 & 0 & \cdots & 0 & 0 \\ 0 & 1 & -1 & \cdots & 0 & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & 0 & \cdots & -1 & 0 \\ 0 & 0 & 0 & \cdots & 1 & -1 \end{bmatrix}. \quad (4)$$

The columns correspond with the number of nodes (or connection points), whereas each row is a segment of the grid (line) between two nodes. The start and end node of each line are represented by respectively

1 and -1. Since a radial grid contains  $n$  nodes, there are  $(n - 1)$  line segments. To attain a square matrix, an additional (first) row is introduced to represent the imaginary line segment between the transformer and the first node (with a length of 0 m). This line segment only has an end node.

## 3.2 Grid elements

### 3.2.1 Cables

Cables, with a length  $f_L$  (m), for the line segments are characterized by an impedance  $Z = R + jX$ , with  $R$  the resistance and  $X$  the reactance of the cable:

$$R = f_L r \quad \text{and} \quad X = f_L x, \quad (5)$$

with  $r$  the characteristic resistance and  $x$  the characteristic reactance in  $\Omega/\text{m}$ . This allows to represent the grid with an impedance matrix  $\mathbf{Z} = \mathbf{R} + j\mathbf{X}$ . Single-phase AC and DC grids contain two conductors, respectively a phase/neutral conductor and a positive/negative (or positive/neutral) conductor. Three-phase grids have three phases and one neutral conductor (total of four conductors).

For three-phase AC cables, typically nominal  $\Pi$  or  $T$  models are used to model cable, which include the resistance and reactance of the cable, as well as the shunt admittance. This capacitance is neglected for the considered low-voltage grids in this paper. Also, it is assumed that all phases are symmetrically spaced and that all phases are regularly transposed. Compared to [13], the shunt admittance and mutual impedance, which has a very small impact for low-voltage cables, is neglected.

### 3.2.2 Transformers

A transformer transforms e.g. a higher to a lower AC three-phase voltage level. The transformer is modeled with a phase impedance  $Z_{tr} = R_{tr} + jX_{tr}$ , which are assumed identical for the three phases. The losses in the transformer  $P_{\text{loss}}$  are the sum of the no-load losses  $P_0$ , which are assumed to be constant, and the sum of the joule losses  $P_J$  in each phase  $f$  of the transformer:

$$P_{\text{loss}} = P_0 + P_J = P_0 + \sum_{f=1}^3 R_{tr} |i_{f,k}|^2. \quad (6)$$

## 3.3 Load models

### 3.3.1 Loads and generation units

Loads and generation units are modeled as constant power loads, which is common for loads equipped

with power electronic. This means the power is not depending on the solution of the power flow (voltage and current). This results in a non-linear relation between power, voltage and current, as shown in Eq. (2) and its implementation in Section 4.2.4. Other possible load models take e.g. grid variables as input, such as voltage-droop load models [16].

### 3.3.2 Converters

Converters are required to convert AC to DC (rectifiers) or vice versa (inverters) or DC to DC. For rectifiers, the DC power ( $P_{DC}$ ) is lower (or equal) than the AC power ( $P_{AC}$ ). For inverters:  $P_{AC} \leq P_{DC}$ . The ratio between the DC and AC power is defined by the efficiency of the converter. The power electronics level of converters is not modeled.

Converters can also regulate the reactive power consumption or injection [13]. The power factor ( $\text{pf} = P/|S|$ ) can be leading (drawing reactive current) or lagging (injecting reactive current).

## 4 Implementation in Modelica

This section gives an overview on the functional requirements of the models, which are identified from the different use cases. In the second part, the component modeling is described.

### 4.1 Requirements

#### 4.1.1 Use cases

This section describes the needs for electrical grid modeling at the level of an individual building and at the level of a district energy system. The following use cases are identified, which are used to define the functional requirements:

- Grid impact analyses of electrical processes at building and district level. The results are an analysis of the nodal voltages, line currents, powers (active and reactive) and power losses.
- Grid architecture: single/three-phase AC grids and DC grids.
- Flexible and scalable approach for grid topology definition for all grid types.
- Connection architecture: Single/three-phase connection for loads and generation units.
- Integrated control or optimization by using grid variables, such as the nodal voltages, powers, etc.

### 4.1.2 Functional requirements

This section describes the functional requirements. Physics to be modeled include:

- Load and generation units:
  - Active and reactive power;
  - Connectors: Complex voltage/current and single/three-phase;
  - Converter losses.
- Electrical grids:
  - Quasi-stationary analysis;
  - Active and reactive power flows and losses;
  - Transformer: voltage drops and losses;
  - Unbalanced loads (including the resulting zero-point shifting);
  - Grid type:
    - \* Distribution and in-building grid;
    - \* Single-phase, three-phase (unbalanced) and equivalent single-phase;
    - \* AC and DC.
  - Integrated control or optimization: access to grid variables.

## 4.2 Modelica model implementation

### 4.2.1 Connectors

The library uses the connectors from the Standard Modelica Library:

- AC connectors: `Electrical.QuasiStationary.SinglePhase.Interfaces.Pin`
- DC connectors: `Electrical.Analog.Interfaces.Pin`

These connectors contain the voltage and current (flow). The AC positive and negative pin also include a reference angle.

The grid contains both *internal* and *external* nodes. The internal nodes include the neutral or negative connector, while the external nodes are used to connect the loads and generation units.

**External nodes** The external connection nodes are defined as: `.Pin Nodes[numPha,nNodes]`, with `nNodes` the number of grid nodes and `numPha=1` for single-phase AC and DC loads and generation units and `numPha=3` for three-phase AC loads and generation units.

**Internal nodes** The internal connection nodes are defined as `.Pin gridNodes[numCon,nNodes]`, with `numCon` the number of conductors (see Section 3.2).

**Adapters** Adapters are available to connect the internal and external nodes (see Code 1). For single-phase and DC grids, the adapter connects the two wire to a single wire system. For three-phase grids these are respectively four and three wire systems. A single-phase load or generation unit can be connected to one phase of a three-phase grid.

Fig. 4 shows the use of an adapter in a three-phase grid to connect the internal (`node4Lines`) and external nodes (`nodes3Ph`). The electricity grid connects the `gridConnection` (e.g. voltage source or transformer) with the internal nodes.

#### Two wires to single wire

```
twoWire[1].v - twoWire[2].v =
  oneWire[1].v "Phase voltage";
oneWire[1].i = -twoWire[1].i;
twoWire[1].i = -twoWire[2].i;
if AC then
  .Connections.branch(oneWire[1].
    reference,twoWire[1].reference);
oneWire[1].reference.gamma =
  twoWire[1].reference.gamma;
end if;
```

#### Four wires to three wires

```
for f in 1:3 loop
  fourWire[f].v - fourWire[4].v =
    threeWire[f].v "Phase voltage";
threeWire[f].i = -fourWire[f].i;
.Connections.branch(threeWire[f].
  reference,fourWire[f].reference);
threeWire[f].reference.gamma =
  fourWire[f].reference.gamma;
end for;
fourWire[1].i + fourWire[2].i +
  fourWire[3].i = -fourWire[4].i;
```

**Code 1:** Adapters for internal and external nodes.

**Figure 4:** Use of adapter for three-phase grids.

### 4.2.2 Grid topology

The grid topology is described by the incidence matrix and the cable impedances (see Section 3). This is shown in Code 2. GridType extends GridImp and describes the grid topology.

Code 3 shows how the grid is constructed by using the incidence matrix. This code is used to construct each phase (and neutral) of the grid by connecting the different line segments (conductor) and grid nodes.

```
record GridType
  extends GridImp (R=CabTyp.RCha.*LenVec,
    X=CabTyp.XCha.*LenVec);
  parameter Modelica.SIunits.Length
    LenVec[nNodes] "Length for each line";
  parameter Cable CabTyp[nNodes];
end GridType;

record GridImp
  parameter Integer nNodes;
  parameter Integer nodeMatrix
    "Incidence matrix";
  parameter Modelica.SIunits.Resistance
    R[size(nodeMatrix,1)];
  parameter Modelica.SIunits.Reactance
    X[size(nodeMatrix,1)];
  parameter
    Modelica.SIunits.ComplexImpedance
    Z[size(nodeMatrix,1)] (re=R, im=X);
end GridImp;

record Cable
  parameter CharacteristicResistance RCha
    "Characteristic resistance";
  parameter CharacteristicReactance XCha
    "Characteristic reactance";
  parameter ComplexCharacteristicImpedance
    ZCha (re=RCha, im=XCha);
end Cable;
```

Code 2: Description of grid topology (interfaces).

### 4.2.3 Grid elements

**Cables** Code 2 also describes the record Cable. This record describes each cable type with their respective characteristic impedance, which is the impedance per unit of length ( $\Omega/\text{m}$ ).

**Transformers** The transformer model consists of an impedance for each of the three phases. The interface for the records, which are used to define the transformer data, is shown in Code 4.

```
For each conductor i
  phase + neutral/negative
  connect (internalNode[i], conductor[i].pin_p);
  for x in 1:nNodes loop
    for y in 1:nNodes loop
      if nodeMatrix[x,y] == 1 then
        connect (conductor[x].pin_p, node[2,y]);
      elseif nodeMatrix[x,y] == -1 then
        connect (conductor[x].pin_n, node[2,y]);
      end if;
    end for;
  end for;
```

Code 3: Connect statements for the grid construction.

```
record Transformer
  parameter Modelica.SIunits.ApparentPower

### 4.2.4 Load models

**Constant power model** Code 5 shows the non-linear relation between the apparent power, voltage and current shown in Eq. (2).

**Converters** The converters are implemented according to Section 3.3.2 and the power equations in Section 2. Fig. 5 shows the diagram for a bidirectional converter, which uses the AC and DC connectors as defined in Section 4.2.1. The AC connector can be single or three-phase. For three-phase converters, the apparent power is equally divided over the three phases:  $S_f(t) = S(t)/3$ .

Figure 5: Use of adapter for three-phase grids.

  inverter = if pDC >= 0 then true
    else false "Define converter mode";
  pAC = if inverter then -pDC*eff
    else -pDC/eff "DC/AC power ratio";
end BidirectionalConverter;

```

**Code 6:** Converter mode and DC/AC power ratio.

### 4.3 Simulation of multiple grid types

The Modelica implementation also allows to simulate multiple types of grid (i.e. single-phase AC, three-

phase AC and DC grids) in one simulation. Fig. 6 shows an example with different grids (with loads) connected to one feeding transformer. For the DC grid, a converter is required as well as a separate DC grounding.

**Figure 6:** Simulation of multiple grid types in one simulation.

## 5 Comparative model validation

The electrical grid models are validated using a comparative validation method. The three-phase grid models from the Modelica library are compared with the power flow analysis tool in [13].

### 5.1 Example case: residential district

A simple case study is developed with a small three-phase unbalanced residential distribution grid.

There is one feeder connected to the feeding transformer. 20 residential loads are connected to respectively one of the 20 nodes in this feeder. The cables between the nodes have a length of 16 m and have a characteristic impedance of  $0.507 + j0.229 \text{ m}\Omega/\text{m}$ . The feeder is connected to a three-phase transformer which has a phase impedance of  $20.4 + j67.5 \text{ m}\Omega$ . The nominal phase voltage between a phase and the neutral conductor is 230 V. The grid topology is illustrated in Fig. 7 (not on scale).

**Figure 7:** Grid topology for the validation model.

Synthetic residential load profiles for one day are available on a 30-minute resolution [17]. A set of 16 different profiles are randomly distributed over the different household connections to the distribution grid. The household loads are all single-phase connected.

## 5.2 Validation results

For the comparative validation, the results on the nodal phase voltages are compared with the results of the models from [13]. Fig. 8 shows the absolute<sup>1</sup> difference in results between the Modelica and Matlab models. Box plots are used to show the difference in the nodal phase voltages during the simulation period of one day for each phase of the electrical grid. The median, minimum and maximum values of these absolute differences are repeated in Table 1.

**Figure 8:** Relative absolute difference on the nodal phase voltages for each phase between the Modelica models and the Matlab models from [13].

**Table 1:** Median, average, minimum and maximum relative nodal voltage difference [%] for each phase.

	Median	Average	Min.	Max.
Phase 1	0.0277	0.0256	0.0009	0.0476
Phase 2	0.0133	0.0121	0.0004	0.0181
Phase 3	0.0144	0.0135	0.0003	0.0292

The average absolute nodal phase voltage differences for a voltage of 230 V are in the order of  $10^{-2}$  V. The minimum difference is less than 1 mV. Note that in this case study the nodal phase voltages are always lower than 230 V since there are only loads.

This difference between both models is function of the loads and the grid topology, since an error in one node will propagate through the grid as a result of the Laws of Kirchhoff in an electrical circuit. Therefore,

<sup>1</sup>The differences are both positive and negative

the difference in results will also increase for nodes further from the feeding point. A second source of the difference in results is the stop criterion for the iteration in both simulations. The Matlab code uses a maximum allowed voltage error (1 mV) as a stop criterion. In Dymola, a tolerance of  $10^{-4}$  is used. A last part of the difference is that the shunt admittance and mutual impedance between cables in three-phase systems is neglected in this Modelica library.

The differences between the results of both models are limited. Since both stop criteria for the iterative solution method is different, the results show that the accuracy is sufficient to apply this Modelica library.

## 6 Conclusions

A Modelica library is developed to simulate single-phase AC radial grids, both balanced and unbalanced three-phase AC radial grids and DC electrical grids. For AC grid analyses, a quasi-stationary model is implemented, assuming a fixed grid frequency (e.g. 50 Hz). The library is based on previous work, in which a library was presented to simulate fully balanced three-phase low-voltage distribution grids [1].

The models in this library can be used for electrical grid systems for low-voltage distribution grids and in-building grids. Electrical grids may connect many different energy systems (loads and generation units), different grids and/or buildings within districts. The library allows to assess the grid impact of these systems. Control or optimization strategies can use grid variables, such as voltages and power exchanges.

The comparative validation of this Modelica library with a power flow simulation in Matlab [13] shows that the difference in nodal voltages depends on the loads, the grid topology and end criterion. Also the mutual impedance of cables in three-phase systems is neglected. Nevertheless, the average voltage differences are limited, for this case study in the order of  $10^{-2}$  V for a voltage of 230 V.

## A Appendix: Backward-forward sweep method

The backward-forward sweep is an example of an iterative method to solve a power flow analysis. The method is well suited for radial grids.

First, an initial guess of the voltage profile is set. This allows the backward step to calculate the nodal ( $I_{\text{node}}$ ) and line currents ( $I_{\text{line}}$ ) in function of the ap-

parent power ( $\mathbf{S}_{\text{node}}$ ), the nodal voltages ( $\mathbf{U}_{\text{node}}$ )<sup>2</sup> and incidence matrix ( $\mathbf{T}$ ), which is defined in Section 3.1:

$$\mathbf{I}_{\text{node}} = f(\mathbf{S}_{\text{node}}, \mathbf{U}_{\text{node}}) = \left( \frac{\mathbf{S}_{\text{node}}}{\mathbf{U}_{\text{node}}} \right)^*, \quad (7)$$

$$\mathbf{I}_{\text{line}} = (\text{transpose}(\mathbf{T}))^{-1} \cdot \mathbf{I}_{\text{node}}. \quad (8)$$

In the forward step, the nodal voltage is calculated with the line currents:  $\mathbf{U}_{\text{node}} = \mathbf{U}_{\text{grid}} - \mathbf{Z} \cdot \mathbf{I}_{\text{line}}$ . The iteration stops when convergence is reached.

## Abstract

This paper describes software tools developed at the Lawrence Berkeley National Laboratory (LBNL) that can be coupled through the Functional Mock-up Interface standard in support of the design and operation of building energy and control systems. These tools have been developed to address the gaps and limitations encountered in legacy simulation tools. These tools were originally designed for the analysis of individual domains of buildings, and have been difficult to integrate with other tools for runtime data exchange. The coupling has been realized by use of the Functional Mock-up Interface for co-simulation, which standardizes an application programming interface for simulator interoperability that has been adopted in a variety of industrial domains.

As a variety of coupling scenarios are possible, this paper provides users with guidance on what coupling may be best suited for their application. Furthermore, the paper illustrates how tools can be integrated into a building management system to support the operation of buildings. These tools may be a design model that is used for real-time performance monitoring, a fault detection and diagnostics algorithm, or a control sequence, each of which may be exported as a Functional Mock-up Unit and made available in a building management system as an input/output block. We anticipate that this capability can contribute to bridging the observed performance gap between design and operational energy use of buildings.

## 1 Introduction

Building thermal systems, ventilation systems, electrical systems and control systems are becoming more and more integrated to increase the energy effi-

ciency and to improve the interoperability with the electrical grid. This leads to a higher level of complexity for the design, installation, commissioning and operation of these systems. Modeling and simulation of such systems is challenging in today's simulation tools because it requires the tool to support multiple physical domains, multi-time scales, and also different formalisms for how systems evolve in time, in particular if they involve supervisory control with state transitions.

At present, the simulation of controls, rapid prototyping of new building energy and control systems and the use of simulation for building operations and building retrofits are constrained by current simulation tools. Most legacy whole building energy simulation tools such as EnergyPlus [1] or TRNSYS [2] perform well for annual energy analysis, but their model representation and numerical methods do not allow simulating systems with fast dynamics nor do they allow the proper representation of controls. For example, in EnergyPlus, the smallest time step is one minute, TRNSYS has a fixed time step, and neither can handle state events. To nevertheless use these tools with other programs that better address controls or systems with fast transients, but may lack comprehensive libraries of building components, they can be coupled with each other through co-simulation. By co-simulation, we mean a technique that allows individual component models described by differential algebraic or discrete equations to be simulated by different simulation tools running simultaneously and exchanging data during runtime.

Co-simulation somewhat remedies the limitations of individual tools. While this allows addressing many practical questions, see [3-5], one has to keep in mind that hybrid systems formed through this tool coupling still have some deficiencies. We refer to [6] for properties that would need to be satisfied by the individual tools to allow a proper treatment of hybrid systems.

This paper is structured as follows: Section 2 introduces the Functional Mock-up Interface (FMI) standard which is the open standardized interface used in this paper for co-simulation. Section 3 describes a) FMIs added to the Building Controls Virtual Test Bed (BCVTB), and EnergyPlus to support their co-simulation with various tools, and b) an FMI added to a building management system to support error-free development and deployment of control algorithms. Section 4 presents our conclusions.

## 2 Functional Mock-up Interface for Co-Simulation

The FMI standard has originally been developed in the Information Technology for European Advancement (ITEA2) project MODELISAR.

The FMI standard supports both model exchange and co-simulation of dynamic models using a combination of XML<sup>1</sup>-file, C-code and/or shared libraries.

The FMI standard version 1.0, which has been used in this contribution, consists of three parts:

- FMI for model exchange, which standardizes an interface for coupling simulation tools that are integrated in time by an external solver [7].
- FMI for co-simulation, which standardizes an interface for coupling simulation tools that contain their own solver for time integration [8].
- FMI for Product Lifecycle Management, which provides a standardized way to handle FMI related data [9].

A system model or simulation tool which implements the FMI standard is called a Functional Mock-up Unit (FMU). An FMU comes in the form of a zip-file, which contains the FMI model description file, which is an XML-file with information needed by an import tool, C-code and/or shared libraries required to interface with the model or simulation tool, and resource files such as tables, or documentation.

This contribution uses the FMI for co-simulation application programming interface (API). This API provides the means for two implementations namely *CoSimulation\_Tool*, and *CoSimulation\_StandAlone*. In the *CoSimulation\_Tool* implementation, the FMU contains a wrapper for shared libraries that interact with the slave tool so that a master tool which im-

ports the FMU can interface with the slave tool in a standardized way. In the *CoSimulation\_StandAlone* implementation, the FMU contains the model and its solver.

## 3 Co-simulation using the FMI Standard

### 3.1 FMU for Co-Simulation Import Interface in the BCVTB

The BCVTB [10] is a free, open-source middleware based on Ptolemy II [11]. It allows users to couple different simulation tools such as EnergyPlus, TRNSYS, MATLAB/Simulink [12], Modelica [13], or ESP-r [14] at runtime for co-simulation. The BCVTB also allows calling system commands, for example to run a shell script, which may start a Radiance-based [15] daylighting simulation. Figure 1 gives an overview of tools coupled to the BCVTB. The BCVTB also allows simulation tools to be coupled with hardware through its BACnet interface or its analog/digital interface [16].

The BCVTB is essentially a special configuration of Ptolemy II, with the addition of actors<sup>2</sup> and examples that are of interest to the buildings community.

The BCVTB has been used in several applications such as agent-based simulation [5], real-time simulation [3], controls of networked sensors and actuators [17], and performance prediction of HVAC systems [18].

As the BCVTB has been developed at the same time as the first version of the FMI standard, it contains its own API for co-simulation. This API is however much more limited than FMI and is not supported by all tools that export FMUs. Therefore, an FMU for co-simulation import interface has been added to the BCVTB. This interface allows the BCVTB to import simulation tools which have been exported as FMUs (Figure 2). This interface complies with the FMI for co-simulation API.

This new capability has several benefits:

- It allows users to couple the simulation tools shown in Figure 1, which are not all available as an FMU, to any other simulator that can be exported as an FMU for co-simulation.

---

<sup>1</sup>XML stands for Extensible Markup Language.

<sup>2</sup>Actors are software components that execute concurrently and share data with each other by sending messages via ports.

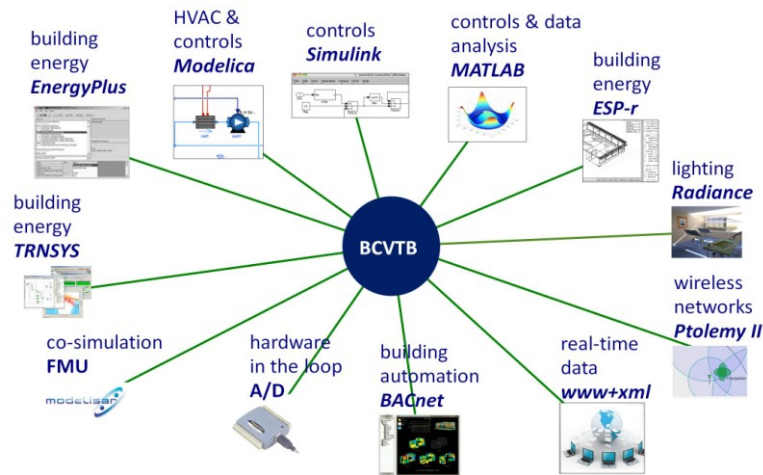

Figure 1: Simulation tools and hardware that can be coupled to the BCVTB.

- The BCVTB can be used as a master algorithm for co-simulation of FMUs using the Synchronous Data Flow domain of Ptolemy II.
- FMUs can be linked to hardware through the BCVTB.
- The BCVTB provides a graphical user interface for linking and simulating FMUs for co-simulation.
- The BCVTB allows synchronizing the simulation of FMUs to real-time.

The use of the BCVTB has the drawback that it introduces an additional transaction layer between the different simulators. As computing time is for most applications dominated by the simulation code inside the FMUs, the BCVTB middleware generally has no noticeable effect on the computing time. However, users need to have some familiarity with the use of the BCVTB. This increases the learning curve and

could be a barrier for users who are familiar with one simulation tool and do not have resources to learn how to use this middleware. In addition, in some use cases, it may be more expedient to work directly in a domain-specific modeling environment. For example, when analyzing different façade systems, one may want to use a graphical user interface of a building simulation program that imports the model of the façade controller as an input/output block. Conversely, when developing a controller, one may want to take advantage of the visual editor and plotting capabilities of a Modelica modeling and simulation environment, while using an input/output block for a building model that takes as input the control action and outputs a sensor signal. For the first use case, we developed an FMU for co-simulation import interface in EnergyPlus, for the second use case, we developed a facility to export EnergyPlus as an FMU for co-simulation. The next two sections describe these technologies.

Figure 2: FMU for co-simulation import interface in the BCVTB.

### 3.2 FMU for Co-Simulation Import Interface in EnergyPlus

EnergyPlus is a whole building energy simulation tool. It is used by engineers, architects, and researchers for the modeling and simulation of energy use in buildings. EnergyPlus was not intended to be used for detailed modeling of airflow, dynamic response of heating, ventilation and air-conditioning equipment, and modeling of control systems other than scheduling of setpoints by simple supervisory control algorithms. To overcome these limitations, EnergyPlus has been coupled to various simulation tools such as COMIS [19], Computational Fluid Dynamics [20], MATLAB [21], or Modelica [22].

LBNL added to EnergyPlus 7.2 and higher an FMU for co-simulation import interface to allow the import of any simulation tool that is available as an FMU for co-simulation (Figure 3). This interface complies with the FMI for co-simulation API.

To facilitate the import of FMUs in EnergyPlus, we developed a utility called FMUParser. This utility is distributed with EnergyPlus and can be found in its *PreProcess* folder. When invoked, it unzips the FMU, extracts relevant information from the model description file of the FMU, and writes this information to a temporary EnergyPlus input file. A user can then complete this temporary input file to create the EnergyPlus input file. This parser has been developed so that users do not need to read the model

description file, which can easily contain more than thousand lines of xml syntax.

To support the import of FMUs, we extended the data structure of EnergyPlus with four new objects [23]. These objects are used to map the inputs and outputs of the FMU to internal EnergyPlus variables once the FMU has been imported in EnergyPlus. We also implemented a set of C-functions which are distributed with EnergyPlus as a shared library. EnergyPlus uses these functions to call the FMI functions of the imported FMU.

Figure 4 shows how the FMU for co-simulation import interface was used to couple an HVAC system, implemented in Modelica and exported as an FMU, to a room modeled in EnergyPlus. This example is described in detail in [24]. The HVAC system computed sensible and latent heat exchange with the room, using the air inlet and outlet as the thermodynamic boundary. The room model computed the temporal evolution of the room air temperature and humidity, using the sensible and latent heat exchange as inputs to its energy balance. The FMU uses as inputs the room dry-bulb temperature (TRooMea), the outdoor dry-bulb temperature (TDryBul), the room air relative humidity (rooRelHum), and the outdoor air relative humidity (outRelHum) to compute the sensible and latent heat exchange (QSensible, QLatent) which are sent to EnergyPlus through its outputs. EnergyPlus uses these values to compute the new room air temperature and humidity.

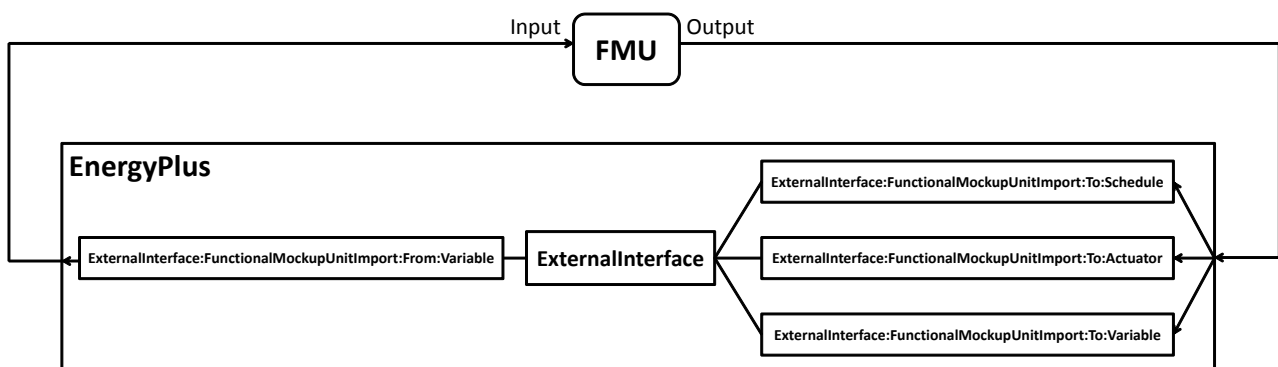

Figure 3: Importing an FMU for co-simulation in EnergyPlus through its ExternalInterface [25].

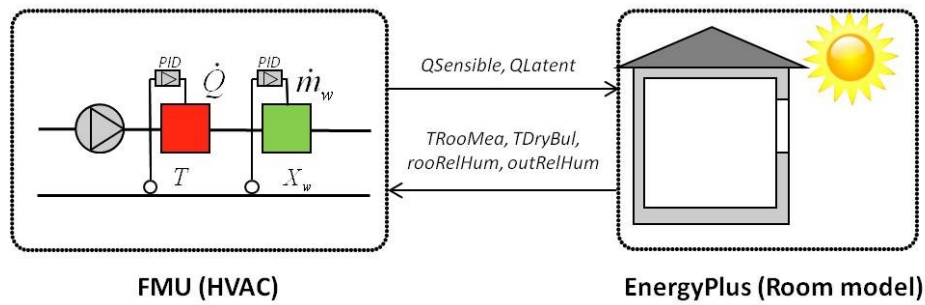

Figure 4: Linking an HVAC model developed in Modelica to an EnergyPlus room model using the FMU for co-simulation import interface.

### 3.3 FMU for Co-Simulation Export Interface of EnergyPlus

Although interfaces and middleware exist that facilitate the coupling of EnergyPlus with various software, they might not be widely used in the building simulation community since they still require users to be familiar with EnergyPlus so they can set it up and link it with other simulation tools. We thus exported EnergyPlus as an input/output block using the FMI standard. This allows importing EnergyPlus into any simulation tool that allows importing FMUs for co-simulation.

To export EnergyPlus 8.0 and higher as an FMU for co-simulation, we developed and released a software module called *EnergyPlusToFMU* [26], which exports EnergyPlus as an FMU for co-simulation. EnergyPlus implements in this configuration the FMI for co-simulation in the *CoSimulation\_Tool* method.

Figure 5 shows how EnergyPlus is imported in Dymola as an input/output block which can be connected to other Modelica blocks.

To support the export of EnergyPlus as an FMU for co-simulation, we extended the data structure of EnergyPlus with four new objects [23]. These objects map the inputs and outputs of the FMU to variables that are internal to EnergyPlus.

Exporting EnergyPlus as an FMU for co-simulation can support various applications. For example, as described above, EnergyPlus may be used as an input/output block when designing a controller in a Modelica modeling and simulation environment or in MATLAB/Simulink. EnergyPlus building models may be linked to electrical grid and control models to design an electrical demand response controller for a campus that controls building electrical loads as a function of tariff, power quality and state of charge of batteries.

Table 1 shows a comparison between the different import and export capabilities. The table also lists their strengths and weaknesses. Although not exhaustive, this table should guide users in the selection of an import or export facility that is adequate for their specific application.

Figure 5: Coupling of an EnergyPlus model exported as an FMU with a PI-controller using Dymola.

Table 1: Comparisons between different technologies to couple simulators<sup>3</sup>.

	Graphical user interface	Minimum knowledge required	Pros	Cons
BCVTB	Yes	BCVTB, and tools to be coupled.	Links to various tools and hardware.  Reuse functionality of Ptolemy II.	Learning curve, transaction layer.
BCVTB (FMU Import)	Yes	BCVTB and FMU.	Links to various tools, FMU for co-simulation and hardware.  Reuse functionality of Ptolemy II.	Learning curve, transaction layer.
EnergyPlus (FMU import)	No	EnergyPlus and FMU.	No need to learn new tool.  May be able to use graphical user interface of EnergyPlus <sup>4</sup> .	Tool to couple needs to be available as an FMU for co-simulation.
EnergyPlus (FMU export)	No	EnergyPlus and FMU.	EnergyPlus can be imported in other tools.  Can use EnergyPlus as an input/output block inside a block diagram editor.	Import tool needs to support FMI for co-simulation.

---

<sup>3</sup>Simulator refers to simulation tool, system model, or tool exported as an FMU for co-simulation.

<sup>4</sup>Not all graphical user interfaces of EnergyPlus may support all EnergyPlus features and thereby support the FMU import interface.

The previous sections described the coupling of multiple simulators. In the next section, we describe an import interface that we implemented in an open framework for building controls that allows linking FMUs for co-simulation with different building management systems.

### 3.4 FMU for Co-Simulation Import Interface in Niagara<sup>AX</sup>

Niagara<sup>AX</sup> is a Java-based framework and development environment for creating internet-enabled products, device-to-enterprise applications and distributed internet-enabled automation systems. It is a commercial product from Tridium that is often overlaid to other building management systems to facilitate their interoperability (Figure 6). Niagara<sup>AX</sup> uses a unified component model (Common Object Model) to transform the data from diverse external systems into uniform software components. These components form the foundation for building applications to manage and control the devices.

LBNL added to Niagara<sup>AX</sup> an FMU for co-simulation import interface. This interface complies with the FMI for co-simulation API.

We selected the Niagara<sup>AX</sup> framework because of its open-source architecture, which is based on Baja (Building Automation Java Architecture) [27] and its wide use in the buildings industry.

To implement the FMI interface in the Niagara<sup>AX</sup> framework, we used JFMI [28], a Java wrapper for FMI, and created two new classes `BFMUService` and `BFMUComponent`. These classes are used in the framework to interface with imported FMUs for co-simulation.

The `BFMUService` is used by the Niagara<sup>AX</sup> framework to process FMUs and to make their relevant information available to the framework. The `BFMUComponent` class represents an FMU instance. When instantiated, it appears in the

Niagara<sup>AX</sup> framework as an input/output block, which can be connected to other components of the Niagara<sup>AX</sup> framework.

Figure 7 shows an FMU for co-simulation which has been imported in Niagara<sup>AX</sup> as an input/output block. This block can then be linked to any other block available in the Niagara<sup>AX</sup> framework.

Adding an FMU for co-simulation import interface enables various applications. For example:

- An HVAC designer may create a simulation model during the design of a building. She/he then exports the model as an FMU for co-simulation and imports it to Niagara<sup>AX</sup>. In Niagara<sup>AX</sup>, she/he links the model input to measured data. The design model can then be used to compute expected energy consumption, which in turn can be used to compare measured with expected performance. See [3] for such a use case.
- A researcher or product developer may develop a fault detection and diagnostic algorithm, test it on a simulation model, and then export the algorithm as an FMU for co-simulation. This FMU can then be linked through Niagara<sup>AX</sup> with an actual building energy system.
- A researcher, product developer or advanced HVAC designer may develop and test an advanced control sequence in simulation, export it as an FMU for co-simulation, and import it to Niagara<sup>AX</sup> to link it to an actual building.

We anticipate that the use of FMI in building management systems supports a robust and low cost implementation, and an error-free deployment of controls or FDD algorithms.

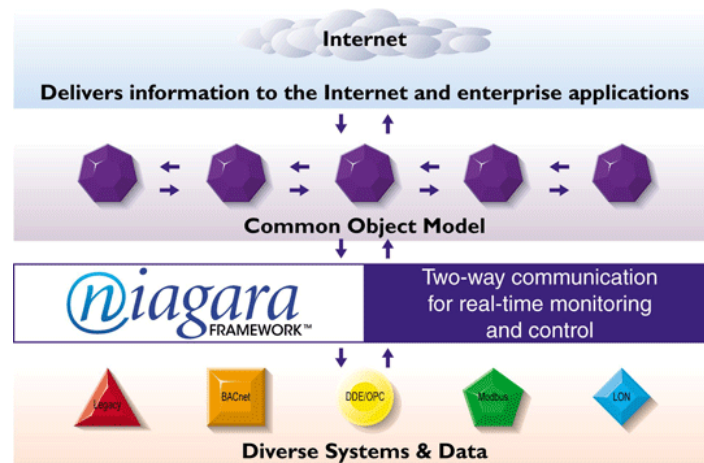

Figure 6: Niagara<sup>AX</sup> framework (Courtesy: Tridium).

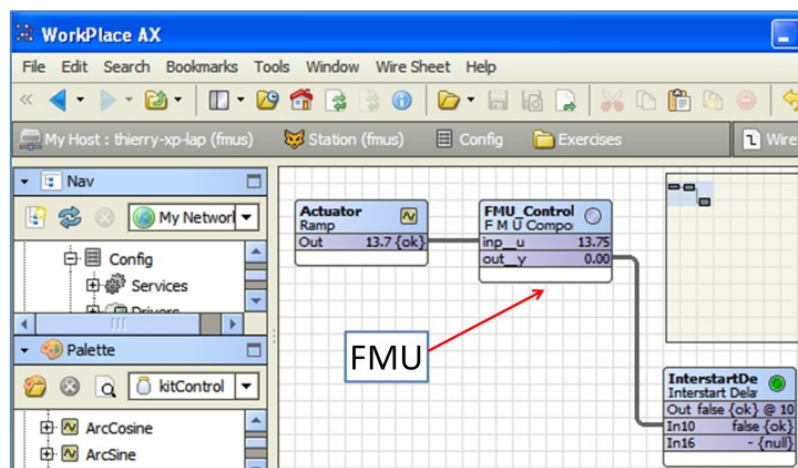

Figure 7: FMU for co-simulation import interface in Niagara<sup>AX</sup>.

## 4 Conclusions

We anticipate the integration of FMU for co-simulation interfaces in the BCVTB and EnergyPlus to support a better simulation-based design and operation of buildings.

We believe FMI to be well positioned to become a de-facto standard for implementing, and deploying control sequences. We thus see the integration of an FMU for co-simulation import interface in building management system as a promising approach and a natural extension of its application to date.

## Acknowledgments

This research was supported by the Assistant Secretary for Energy Efficiency and Renewable Energy, Office of Building Technologies of the US Department of Energy, under Contract No. DE-AC02-05CH11231.

We thank Pacific Controls for sponsoring the development of a Functional Mock-up Unit for co-simulation import interface in Niagara<sup>AX</sup>.

We thank Edward A. Lee, Christopher Brooks, David Broman, and Stavros Tripakis from the University of California at Berkeley for their support in developing JFMI and implementing the Functional Mock-up Unit for co-simulation import interface in the BCVTB.

## Abstract

This paper illustrates the use of *Functional Mock-up Interface* (FMI) [1] to couple an occupant behaviour simulator and a building model.

Due to their intrinsic nature, occupant behaviour and building and its energy systems are usually represented by different modelling paradigms. The occupant behaviour is here described by Agent-Based Modelling (ABM) whereas the building is described by a set of hybrid and differential algebraic equations, typical of dynamic thermal modelling. Such different complex systems cannot be efficiently simulated in a single tool. Therefore, one solution is the tool coupling approach.

The FMI standard for co-simulation was used to couple the SMACH occupant behaviour simulator and a building energy model built with the BuildSysPro Modelica library. Variables of interest are passed from one model to another at fixed synchronization time steps.

*Keywords: Building simulation; behavioural modelling; Specific use of electricity; thermal comfort; Modelica; FMI; co-simulation*

## 1 Introduction

Enforcement of energy efficiency policies drives new buildings towards better performance and especially low or even positive energy buildings. These kinds of buildings are different from existing ones as their ventilation and envelope heat losses are intensively decreased. Nevertheless, this improvement has two consequences. First, human actions to ensure thermal comfort can cut back heating and cooling energy savings. Second, a significant share of energy will be consumed by specific electricity uses (light-

ing, cooking, white goods, electronic appliances...) and not anymore by space heating and cooling. Both points are strongly linked with occupant behaviour.

Occupant behaviour is commonly described in dynamic building simulation tools using standardized occupancy profiles. Various studies suggest that occupant behaviour should be taken into account in a more accurate way, as it can have a dramatic impact on energy consumption especially in the context of low and positive energy buildings [2] [3].

The purpose of this work is to couple realistic occupant behaviours with building energy simulation. It focuses on dynamic modelling and especially electric power demand instead of energy consumption. Two interaction approaches were carried out:

- Co-simulation for R&D studies,
- Generation of realistic occupancy scenarios for simplified building simulation tools.

This last objective will be fulfilled thanks to design of experiments using the co-simulation. Only the tool-coupling approach is presented here.

## 2 Occupant behaviour model

The occupant behaviour model is implemented in the SMACH platform, an agent-based tool developed by EDF and the LIP6 laboratory.

The coupling between the building energy model and the occupant behaviour model is mainly carried out through thermal comfort perception and control of electrical appliances.

### 2.1 Occupant behaviour model

In order to represent adequately and individually the behaviour of each occupant, we rely on an agent-based modelling approach and, more specifically, the

one we already applied in [4]. The agents, in SMACH, provide a realistic way of modelling inhabitants' behaviour. In the occupant behaviour model, an agent corresponds to an individual person, and a family corresponds to a group of agents. This modelling approach emphasises the fact that agents are autonomous and have their own individual interaction dynamic within the situation. At each moment, their universe is defined by their individual perception of the situation, their comfort level and their preferences regarding possible actions [5]. State-graphs could have been used however this kind of approach is much less adaptable and concise than ABM for occupant behaviour modelling.

In practice, the inhabitants' activity is decomposed into generic tasks ( $t$ ) such as "watch TV" or "cook dinner". The actual behaviour of each individual is a set of actions ( $a$ ) derived from the generic tasks. A task is a tuple  $(\tau_{\min}, \tau_{\max}, E_t, E_{tf}, T_{pre})$  corresponding respectively to minimal and maximal duration to conduct the task, the required and favourable appliances and the pre-conditional tasks. For instance, ironing may require the completion of cleaning clothes, lasts one to two hours, requires the iron appliance and may be likely to be conducted with the TV switched on.

An action is an instantiation of a task by an occupant. It is defined by a tuple  $a = (t, w, st)$  corresponding respectively to the associated task, rhythm and its state (done, not-done). A rhythm ( $w$ ) is a tuple  $(per, freq, var, PP)$  corresponding respectively to the base period (day, week, month, year), the frequency, the frequency variability and a set of preferred periods (PP). An action example could be as follows: a child may watch TV according to a weekly rhythm of 10 viewing periods on weekdays between 7 and 8 a.m. and/or 5 and 6 p.m.

## 2.2 Thermal comfort model

The thermal comfort model used in the occupant behaviour simulator is derived from Fanger's PMV model [6]. Instead of defining a mean comfort value, an individual thermal comfort level is defined after the same set of variables (air temperature, radiative temperature, humidity, metabolic heat production and mechanical work). A new parameter called *frilosity* defined by expert assessment and based on field studies in real situation is also taking into account. It describes the cold tolerance of each occupant [7]. On top of this individual model, a group comfort level is defined per room as follows:

$$GC = \sum_{i \in n} \frac{comfort_i \cdot age_i}{n}$$

Where  $age_i$  is the age class and  $comfort_i$  the individuals comfort. The age class defines a level of responsibility depending on age, for instance an adult will favour a child comfort instead of his/her. This group comfort level is used to determine what action the group will choose (e.g. increase temperature set point, open windows) and individuals' actions (e.g. adapt clothing, change activity ...).

## 2.3 Appliances

Electrical appliances,  $e \in E$ , are defined by their electrical power consumption  $\theta_i$ . The *power* function defines this relation for each appliance.

$$power : \begin{cases} E \rightarrow \mathbb{R}^+ \\ e \mapsto \theta_i \end{cases}$$

We consider two types of electrical appliance: *state-based appliances* and *program-based appliances*.

*State-based appliances* are defined as a tuple  $(\theta_o, \theta_s, st)$  where  $\theta_o$  and  $\theta_s$  are the electrical power consumptions when  $e$  is running or in standby mode, and  $st \in \{\text{off, standby, on}\}$  is the state of the appliance, modified by occupants in the house during their activities. Heaters, TVs, fridges... can be represented by state-based appliances.

*Program-based appliances* are defined as an ordered pair  $(P_e, st)$  where  $P_e$  is a set of operating programs characterised by load curves. The status  $st$  of the appliance is then defined by an ordered pair  $st = (p, t)$  where  $p$  is the currently selected program and  $t$  is the time since the beginning of this program. A program  $p$  is an ordered pair  $(\tau, \varphi)$  where  $\tau$  is the program duration and  $\varphi: [0, \tau] \rightarrow \mathbb{R}^+$  gives the appliances power consumption over time during the program. Thus,  $power(e) = \varphi_p(t)$ . For instance, washing machines can be represented by this kind of appliance.

In SMACH, all energy consumption profiles come from real data from the REMODECE European project [8].

## 3 Building energy model

The building energy model is written in Modelica language with the BuildSysPro library developed by EDF [9]. We used a purely thermal model compliant with the *Thermal.HeatTransfer* class from the Modelica standard library. The class is defined by its connector involving the temperature  $T$  as a potential and  $Q\_flow$  for the heat flow rate.

### 3.1 Building envelope

The “Mozart” house is one of the most representative houses in the French residential building stock, and was therefore chosen for this work. It is a medium size detached house of 100 m<sup>2</sup> of living surface area and an air volume of 252.15 m<sup>3</sup>.

The building is modelled in a low energy configuration: the U-values of the different envelope components are low compared to the standard French building stock. Internal wall insulation is chosen since this is the most common in France; it impacts the potential of heat storage into walls. The internal walls are modelled in the same way as the other opaque walls. Therefore, they contribute to the thermal inertia.

**Table 1: Main parameters of the building envelope**

PARAMETER	VALUE	UNIT
$U_{\text{outdoor wall}}$	0.27	[W.m <sup>-2</sup> .K <sup>-1</sup> ]
$U_{\text{ceiling}}$	0.191	[W.m <sup>-2</sup> .K <sup>-1</sup> ]
$U_{\text{floor}}$	0.263	[W.m <sup>-2</sup> .K <sup>-1</sup> ]
$U_{\text{windows}}$	1.43	[W.m <sup>-2</sup> .K <sup>-1</sup> ]

Windows are double-glazed, with no thermal inertia. The conductive, convective and radiative heat transfers are considered.

The building envelope model is composed of six zones corresponding to the different rooms represented in Figure 1. The garage is not taken into account.

### 3.2 Boundary conditions

Weather data is applied as boundary conditions on the outdoor side of the building model. The building envelope is studied in a temperate climate, more precisely the weather data from Trappes, a city lo-

cated near Paris in France. The weather reader model provides the outdoor dry air temperature, the direct and diffuse solar radiations and the sky temperature. Relative humidity and wind data (velocity and direction) are not used in this first study.

The short wave radiations transmitted inside the building envelope through the windows are entirely absorbed by the floor. The long wave radiative heat transfers which occur between the sky and surroundings and the external surfaces of the walls and windows are taken into account through a combined heat transfer coefficient.

### 3.3 Model inputs

Internal heat gains due to the occupants are set to 90 W.pers<sup>-1</sup>. The indoor occupancy scenario is coupled to the occupant behaviour model, impacting internal gains and set point temperatures, which are specified in each zone by the occupants depending on their thermal comfort perception. Occupants also have the possibility to open windows if needed to ensure their comfort. The window open/closed status has an impact on the internal gains by adding a heat gain or loss, depending on the external weather conditions.

### 3.4 HVAC system

The HVAC system is composed of an ideal electrical heater controlled by PID and a mechanical ventilation. A static model is used for the ventilation system with a fixed air change rate.

Considering the weather conditions of Trappes and a normative scenario for occupancy specifying internal heat gains, the annual heat demand for this building is 20 kWh.m<sup>-2</sup>.year<sup>-1</sup>.

**Mozart**

**Figure 1: Diagrams of the Mozart house**

Figure 2 shows the overall Modelica model.

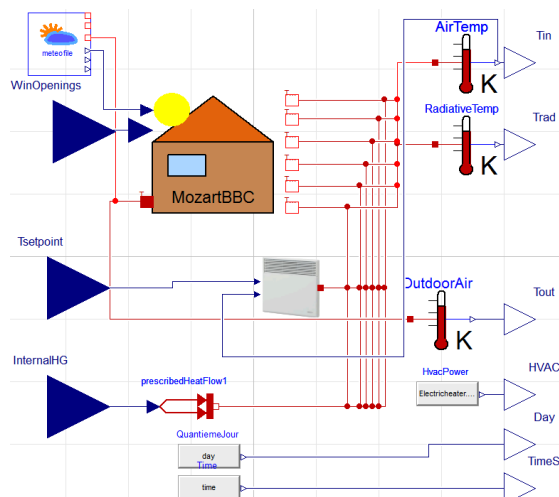

Figure 2: Overall building energy model

## 4 Co-simulation

As previously mentioned, the model describing the building and its energy system has been developed using the BuildSysPro library with Dymola 2014. The occupant model has been implemented within the SMACH agent-based simulation platform, written in Java. In order to allow co-simulation of heterogeneous simulators, the Modelica building model was exported from Dymola as a *Functional Mock-up Unit* (FMU), based on the *Functional Mock-up Interface* (FMI) for co-simulation standard. This approach has already been applied in several works [10] [11].

### 4.1 Implementation

FMI defines a standardized interface to be used in computer simulations to develop complex systems [1]. In practice, it defines a common interface to control the FMU as a dynamic library, a *.dll* file in the present case. The first version of the standard was used.

The master algorithm part is integrated into the SMACH occupant simulator. The JFMI wrapper [12] was used to control the exported FMU within the SMACH platform. It is designed to facilitate control of a native library with Java. A centralised architecture was used with a single FMU representing the entire building with its energy systems. The SUN-DIALS CVODE solver with backward differentiation formula [13] was integrated as the built-in solver of the FMU.

### 4.2 Coupling variables

Several coupling variables are selected in order to couple the building energy model and the occupant simulator. On one hand, the occupant simulator must supply data that can impact the thermal ambiance of each room in the building or the HVAC system. On the other hand, the building energy model must return information to estimate the overall power load and the thermal comfort of the occupants. Therefore the FMU inputs are:

- The temperature set point of each room where occupants can set the temperature.
- The internal heat gains due to appliances and occupancy.
- The windows opening status.

The FMU outputs are:

- The air temperature in each room.
- The mean radiative temperature in each room.
- Outdoor temperature.
- Electrical power consumption of the HVAC system

There are also two optional outputs to ensure proper synchronisation:

- Day
- Time in second

### 4.3 Workflow

The master algorithm acts as a scheduler between the FMU and the occupant model within the SMACH platform. We use a constant synchronization time step of 1 minute. After the instantiation and initialisation steps, the workflow is the following:

1. The behaviour of each occupant is computed based on his/her perceptions (action of other individuals, temperature of the room...) and internal state (action that he yet has to perform, thermal comfort level...).
2. The FMU inputs corresponding to occupants' actions on thermal environment are set (heater control, opening of the windows...).
3. The building energy model computes the actual temperatures based on the occupants actions and their presence (internal heat gains)
4. The FMU outputs are returned to the occupant simulator.

### 4.4 Computing performances

On a computing time point of view, the coupling is heavy. For a one month simulation and a time step of 1 minute, the occupant behaviour simulation takes 3 minutes with SMACH and the building energy simulation takes 10 seconds with Dymola. When coupling

is applied, the same simulation takes 13 minutes. These computing times have been obtained with standard laptop equipped with an Intel i5 2520 M processor on Windows 7 32 bits. These are rough results and no optimisation has been conducted yet.

## 5 Results

This section shows some outputs from the co-simulation between SMACH and the BuildSysPro building model.

The activity diagram in SMACH, Figure 3, is used to analyse simulations. Activities are represented by different colours for each occupant over time.

**Figure 3: Activity diagram, a working day pattern**

On Figure 4, the activity diagram clearly shows the difference between usual working days and other days (Wednesday and weekend) for this household.

Figure 5 shows the temperature evolution over thirteen days including seven days of vacation. The blue line represents the outdoor temperature and the red line, the indoor temperature in the living room. The grey stripes show when the HVAC system is working.

In fact, the actual temperatures and power consumption curves differ because during regular periods, the

family is not at home during weekday daytime and sets the objective to 18°C whereas the indoor temperature is set according to each individual/group comfort level when they are at home. On the contrary, during holidays the indoor temperature is set at 12°C thus, the electric heater power load is null for an extended period of time (due to the efficiency of the represented low energy house) and then can oscillate to maintain this temperature. One may also observe the difference between weekdays and weekends. The absence of occupants during weekdays lets the HVAC system controls the temperature according to the temperature set points.

## 6 Conclusion

This paper presents the first results of the co-simulation between the SMACH platform for occupant behaviour and a BuildSysPro building model. The tool coupling is fully functional, however to ensure computer time efficiency and adaptability the following improvements will be considered in IEA Annex 60 [14]:

- Control of the communication step size,
- Dividing the Modelica model into sub-models (HVAC system, building envelope) and use composition of FMUs to ensure adaptability,
- Auto-mapping of coupling variables, considering input and output names and dimensions,

The authors would like to thank the ANR for funding the SUPERBAT project.

## Abstract

In this work, the structure of a modular, acausal and reconfigurable electro-thermal battery model is described. The dynamic model structure adopted for the battery cell is based on an equivalent circuit whose parameters are generated using real cycling data through an optimisation routine written in the Modelica language. A linearised one-dimensional thermal mathematical model with lumped parameters is used to simulate temperature profiles for the cell. The cell and scaled-up pack model is parameterised for a number of commercially available cells ranging a number of cell formats, sizes and chemistries. These Dymola models are validated using highly transient and aggressive real-world as well as synthetic drive cycles.

*Keywords: Lithium ion, battery, HEV, EV, PHEV, Acausal, Dymola, Modelica*

## 1 Introduction

A key enabler (or constraint) of the electrified power train is the need to store energy in a form that can be easily and robustly converted into electricity. Batteries have emerged as a preferred choice in alternative energy storage but the technology still comes with significant compromises for the customer. Many of the challenges and opportunities presented by battery technology can be traced to the Li-ion cell at the heart of the battery.

The need to accurately, rapidly and robustly model the performance of cells and their effects on the battery system and wider vehicle is of paramount importance to vehicle OEMs. While multiple modelling approaches are available for Li-ion cells, a balance is required to produce a model that has the flexibility to map the microscopic scale effects of internal cell mechanisms to the macroscopic scale of pack and vehicle dynamics in a timely and cost effective manner.

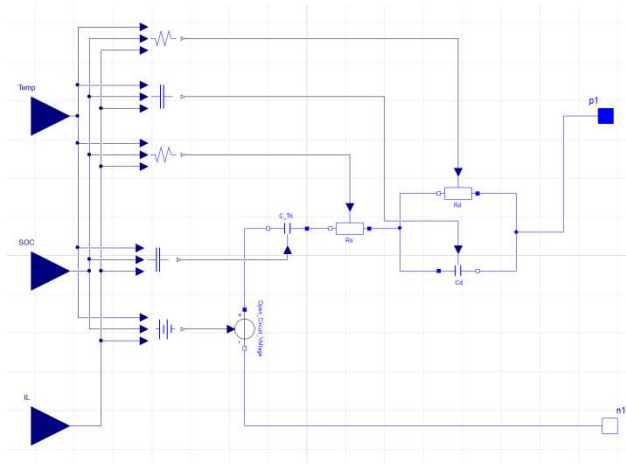

Moreover it is important for any of these battery models to be readily integrateable with an existing electrified powertrain and control simulation toolset, where an acausal simulation structure (as opposed to input-led) can be advantageous. In this paper, we extend the INEEL FreedomCar program model [1] to include temperature dependence, voltage hysteresis, self-discharge and diffusion limitation. We present a generic routine that can be used to generate model parameters based on optimisation [2]. Moreover, we utilise the capacity of Modelica to avoid assignment statements and base our model on equations so as to achieve acausality. Finally, we show an efficient method for scaling-up the cell electro-thermal model, while maintaining the ability to uniquely parameterize individual cells, to pack level without substantially compromising simulation time.

## 2 Model development

### 2.1 Cell Model

Modelling the electronic and thermal behaviour of a battery cell requires characterization of mechanisms across multiple time domains and model parameters that are dynamically interlinked. The equivalent circuit model (ECM) adopted in this work is shown in Figure 1 and consist of a parallel RC network connected in series with a capacitor, a resistor and an ideal voltage source. As shown in Figure 1, the circuit is mainly composed of three parts including an open-circuit voltage source  $V_{oc}$ , internal resistances and equivalent capacitances. The internal resistances include the ohmic resistance  $R_0$  which comprises all electronic resistances and the polarization resistance  $R_d$  which when coupled with  $C_d$  accounts for ion diffusion. The equivalent capacitance  $C_{Th}$  is used to describe the transient response during charging and discharging [1].

**Figure 1:** Depicting the equivalent circuit model of a Li-ion battery system. The circuit represents temperature, state of charge and current dependency of the circuit components; self-discharge and the hysteresis effects added with open circuit voltage.

The electrical behaviour of the ECM shown in Figure 1 is given by [1]:

$$\begin{aligned} V_L &= V_{oc} - I_L R_0 - U_{Th} - U_d \\ \frac{d}{dt} U_d + \frac{U_d}{R_d C_d} &= \frac{I_L}{C_d} \\ \frac{d}{dt} U_{Th} &= I_L \frac{dV_{oc}}{dQ} \end{aligned} \quad (1)$$

where  $V_L$  is the terminal voltage,  $I_L$  is the load current,  $U_{Th}$  is the voltage drop across the capacitor  $C_{Th}$ ,  $U_d$  is voltage drop due to polarisation effects and  $Q$  is accumulated charge; the mentioned variables are time dependent. This coupled set of equa-

tions (1) can be solved analytically and without loss of generality the solution is given by:

$$\begin{aligned} V_L &= V_{oc} - I_L R_0 \\ &\quad - \frac{1}{C_{Th}} \int I_L dt \\ &\quad - \frac{e^{-\frac{t}{R_d C_d}}}{C_d} \int e^{\frac{t}{R_d C_d}} I_L dt \end{aligned} \quad (2)$$

The last term on the right hand side arises from the RC component and is decoupled from contributions from the other components in the circuit. This suggests that from a mathematical viewpoint introducing more RC terms into the ECM will not lead to challenging parameterization algorithms, however, in so doing one must give attention to balancing the computational effort with accuracy yield. In this work we consider a single (modified) RC circuit, similar to that proposed by INEEL FreedomCar program [2], and will show that this leads to sufficient accuracy.

Equation (2) can be re-written in a closed form thus [2]:

$$\begin{aligned} V_L &= V_{oc} - I_L R_0 - \frac{1}{C_{Th}} \int_{t_0}^{t_f} I_L(t) dt - I_P(t) R_d, \quad (3) \\ I_{P,i} &= \left[ 1 - \frac{1 - \exp\left(-\frac{\Delta t}{\tau_P}\right)}{\frac{\Delta t}{\tau_P}} \right] I_{L,i} \\ &\quad + \left[ 1 - \frac{1 - \exp\left(-\frac{\Delta t}{\tau_P}\right)}{\frac{\Delta t}{\tau_P}} \right] \\ &\quad - \exp\left(-\frac{\Delta t}{\tau_P}\right) I_{P,i} \\ &\quad + \exp\left(-\frac{\Delta t}{\tau_P}\right) I_{P,i-1} \end{aligned}$$

which is written in matrix form:

$$\begin{pmatrix} V_{L,1} \\ V_{L,2} \\ \vdots \\ V_{L,n} \end{pmatrix} = \begin{pmatrix} 1 & I_{L,1} & Ah_{L,1} & I_{P,1} \\ 1 & I_{L,2} & Ah_{L,2} & I_{P,2} \\ \vdots & \vdots & \vdots & \vdots \\ 1 & I_{L,n} & Ah_{L,n} & I_{P,n} \end{pmatrix} \begin{pmatrix} V_{oc} \\ R_0 \\ C_{Th}^{-1} \\ R_d \end{pmatrix} \quad (4)$$

where

$$Ah_{L,i} = \sum_{k=0}^i I_{L,k} \Delta t. \quad (5)$$

Solving equation (4) via an optimisation routine in Modelica, which constitutes a part of the battery library, generates estimates for the parameters of the ECM at a fixed temperature ( $T$ ), load current and state of charge ( $SoC$ ) defined by

$$SoC = SoC(t_0) - \frac{100}{Q_{rated}} \int_{t_0}^{t_f} (I + S_D) \cdot dt \quad (6)$$

where  $Q_{rated}$  is the rated capacity of the cell (the total amount of charge that can be reversibly cycled from the cell) and  $S_D$  is the self-discharge contribution given by [3]:

$$S_D = k_0 \left( -\frac{E_A}{R_g T} \right) SoC \quad (7)$$

where the ratio of activation energy to the molar gas constant  $E_A/R_g$  is determined through observations and on timescales of a few hours can be taken to be zero. The optimisation routine runs a sweep for  $\tau$  within a range of values. The value of  $\tau$  which yields the least error when predicting  $V_L$  via equation 4 is selected for the reference data set.

The optimisation routine is repeated for various temperatures, current pulses and  $SoC$  values to produce a three dimensional map of battery parameters as a function of  $SoC$ ,  $I_L$  and  $T$ . These parameters are then fed into the equivalent circuit models.

The Hysteresis contributions  $V_h$  to cell voltage is modelled by the following first-order differential equation which we couple to open circuit voltage  $V_{oc}$  [4]:

$$\frac{\partial V_h}{\partial t} = -\beta(I_L - \epsilon S_D)[V_{h,max} + \text{sign}(I)V_h] \quad (8)$$

where the constants  $\beta$  and  $\epsilon$  are to be determined and  $V_{h,max}$  is the limiting hysteresis voltage. Equation (8) is constructed such that for prolonged as well as large pulse charge currents the hysteresis voltage tends to  $V_{h,max}$  while for prolonged as well as large pulse discharge currents the hysteresis voltage tends

to  $-V_{h,max}$ . Moreover, if there is a prolonged period of zero current the hysteresis voltage tends to  $-V_{h,max}$  through the self-discharge effect.

The  $RC$  component shown in Fig 1 attributes a time constant  $\tau = R_d C_d$  to the bulk diffusional process of Li ions in the solid phase. We account for diffusion limitation, where the surface concentration of lithium may be significantly different than the average concentration contained within the active material particle, by allowing the time constant to be a function of current and assume the following simple power-law form [5]:

$$\tau = |a_0 + a_1 I_L + a_2 I_L^2 + a_3 I_L^3 + O(I_L^4)| \quad (9)$$

**Figure 2:** A comparison of  $V_{oc}$  estimation using polynomial fitting (6<sup>th</sup> order) and spline functions applied to  $V_{oc}(SoC)$  values generated through solving Eq. (4).

To generate mathematically smooth estimates for the battery parameter ( $Y = Y(SoC, I_L, T)$ ) the usual practice is to use polynomial fitting functions. This method has the disadvantage that it often does not fit the data well as in the case of Open Circuit Voltage depicted in Fig. 2. In this work we utilize spline functions to generate smooth estimates for  $Y(SoC, T)$  which avoid oscillations in interpolated values either side of outliers. We find that while both estimates follow the general trend of the data in the highly non-linear regions of the curve the accuracy of the spline function is much greater compared to a polynomial fit.

Cubic splines are preferred over lower degree splines. With first-degree splines the slope of the spline may change abruptly at the knots (i.e., data points) and for second-degree splines the discontinuity is in the second derivative which means that the curvature of the quadratic spline changes abruptly at each node. The cubic spline function  $S$  is de-

defined in the  $X$  interval  $[X_o, X_f]$  such that  $S$  is a polynomial of degree at most 3 on each subinterval  $[X_i, X_{i+1}]$  and  $S$  is continuous up to its second derivative.

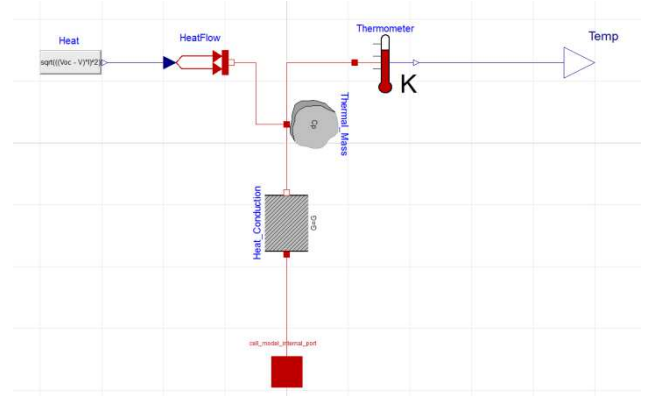

Spline interpolation is coupled with linear interpolation where there is a weak correspondence between a variable  $\{SoC, I_L, T\}$  and the model parameter  $Y = \text{ter } Y = Y(SoC, I_L, T)$ .

A further improvement in stability was achieved using Akima splines. The calculation of the derivative only relies on data from local points, hence reducing the amount of oscillations between data points in the interpolation.

Temperature is modelled as lumped value. For modelling Li-ion batteries this is convenient because of the resulting simplicity of the governing equations. Such assumptions can be suitable if temperature gradients within the cell body are negligible [5] which does not hold for most HEV applications where currents are large. It has recently been shown that a cell with a temperature gradient maintained across it has a lower impedance than one held at the theoretical average temperature [6]. Our assumption therefore will introduce some errors in voltage predictions but this, as will be demonstrated, can be negligible. The thermal model for a single cell is depicted in Figure 3 where the heat generated in  $[J]$  is given by:

$$\dot{Q} = I \left( V - V_{OC} - T_{ref} \frac{dV_{OC}}{dT} \right) \quad (9)$$

where a dot represents a time derivative and  $I(V - V_{OC})$  represents irreversible joule heating caused by Li-ion transport. The last term on the right hand side of Eq. (9) represents the reversible rate of heat generation due to entropy change. This model assumes no specific geometry for a single cell beyond a total volume with uniform temperature for some arbitrary body.

**Figure 3:** Figure depicting the 1D thermal model which is coupled to the electrical model via the heat source (equation 9).

## 2.2 Pack Model

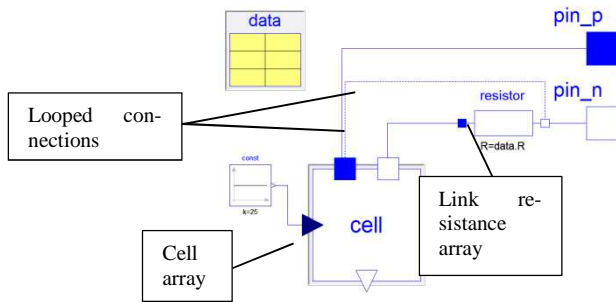

The pack model consists of an electrical network and a thermal network connecting electrical and thermal paths respectively.

### Pack electrical model

A *pack* is constructed from *modules* which are constructed from *sub-modules*. The *sub-modules* are of two types: only parallel connections and only series connections. This allows us to make effective “cells” which become the building blocks of our model. The *sub-modules* are constructed by appropriately looping electrical connections of a single cell. Each cell is then allowed to be unique, i.e., take unique values of initial *SoC*,  $C/3$  discharge capacity, internal resistance, polarisation resistance,  $V_{OC}$ , bus bar connection resistance – through a data table. Such uniqueness of cell parameters allows for various interesting studies including cell balancing, diagnostics, performance limitations, design optimisation and so forth. The *sub-modules* are either connected via parallel or series loops to construct *modules* which can be connected to construct a *pack*. The unspecified parameters of the pack electric model include bus-bar resistance and inter-module connection resistance. For studies of high frequency ripple, the inductance of bus bars can be included as a parameter; however, in what is presented here this option is deselected.

The advantages of using component arrays over separate instantiations of components is firstly: less model diagram layer space being taken up, but more importantly: the ability for the model to be scaled up

or down without having to manually redefine the architecture.

**Figure 4:** Dymola model diagram layer showing component array methodology for scalable stacks.

In the example shown in Figure 4, each element in the cell and resistance arrays (size=n) have been linked using the following notation:

```
connect(pin_p, cell[1].pin_p)

for k in 2:data.n loop
    connect(resistor[k -
        1].n, cell[k].pin_p)
end for;

connect(resistor.p, cell.pin_n)
connect(resistor[data.n].n, pin_n)
connect(const.y, cell.Temp)
```

Symbolic Manipulation is a powerful tool used to simplify the systems of equations generated for a model during compilation. The model equations are rearranged into a form where the unknowns can be calculated whilst the redundant equations are removed. Dymola like other Modelica based tools has its own version of Symbolic Manipulation which helps achieve time-effective model computation.

The simplification of the systems of equations leaves the accuracy of the model intact whilst dramatically reducing the computational effort required to solve the original model equations [7].

### Pack thermal model

Akin to the electrical pack model we connect thermal paths between cells via *heat-ports*. Thus, employing loops we thermally connect *cells* within *sub-modules*, *sub-modules* within *modules* and *modules*

within a *pack* which is attached to a global cooling circuit. In our work we consider two cooling models:

### Control based ideal cooling system

This simple model mimics an ideal cooling strategy. The cooling system remains inactive as long as the temperature of the cells in the pack remains below some critical temperature  $T_c$  (a design parameter). As soon as the temperature exceeds  $T_c$  the cooling system takes action: it extracts heat  $Q(T)$  [W] away from every cell in the pack uniformly. The function  $Q(T)$ , which is a function of cell temperature, can take any form and in the simplest design will be a constant (i.e., regardless of how hot the cells are, the cooling system exerts the same effort). Once the temperature is forced below  $T_c$  the cooling system will return to its idle state.

### Fluid based Cooling Model

This model couples simple fluid dynamics with the existing electro-thermal model. This model connects every cell in the pack via their sub-modules and modules to the global cooling circuit via cooling plates. The surface area of the cooling plate is a critical feature and is a parameter of the model. The cooling system is traversed by coolant (incompressible mixture of water and ethylene glycol, the ratio of which is a parameter of the model) that is forced by an ideal pump with a mass flow rate  $m_{flow}$  that is a parameter of the model.

### 3 Validation

We have parameterized our model for a number of commercially available cells ranging a number of cell formats, sizes and chemistries including cells with Lithium iron phosphate (LFP), Manganese spinel (LMO) and Lithium nickel manganese cobalt (NMC) cathode materials and graphite and Lithium titanate (LT) anode materials. We find cells with the same chemical compositions have similar  $V_{OC}(SOC)$  profiles; however, internal resistance – which is influenced by factors such as electronic contact between active electrode materials and current collectors, homogeneity of the active material paste, the battery internal structure – and polarisation re-

sistance – influenced by electrolyte composition – are found to differ. It can thus be established that the manufacturing process itself will have a bearing on a batteries performance characteristics.

In what follows of this sub-section we present some validation results for the electro-thermal cell model. While the model has been validated for a number of commercially available cells here we present results for a 20Ah LFP pouch cell. The cells were cycled and monitored using a Bitrode MCV 16-100-5 EV/HEV Battery Cell Test System.

### 3.1 Cell level validation

The validation of the 20Ah LFP cell utilised an aggressive artificial cycle, shown in Figure 5a, in order to test the model boundaries. The subsequent results of the electro-thermal model are shown, with laboratory test data, in Figures 5b-5c.

**Figure 5a:** Depicts a highly demanding current profile used for this validation process. The duration of this cycle is 600 seconds (excluding rest time) and the pulses range between 20C discharge and 10C charge.

**Figure 5b:** A comparison of predicted terminal voltage using the cell model (blue line) with actual test data (red line) for a 20Ah LFP cell. The maximum transient error is less than 50mV.

**Figure 5c:** A comparison of temperature predictions using the reduced order model (red line) with laboratory data (blue line) for an A123 20Ah LFP cell.

### 3.2 Pack level validation

For pack validation we use a commercial pack comprising 214 20Ah LFP cells in a 2p107 configuration. The cells are organised into 5 modules: 4 modules with 2p24s configuration and a final module with a 2p11s configuration. There is a service break that splits the pack between 2 modules and 3 modules (2p48s and 2p59s) for safety. The cells are welded to the bus bar by laser welding and the modules are connected via thick 48mm cables with a resistance of  $240 \times 10^{-8} \Omega$  and inductance of 50nH. The pack was cycled and monitored using a Bitrode FTF-500-900 EV/HEV Battery Pack Test System and temperature was recorded using t-type thermocouples connected to a pico logger.

The pack was cycled with a number of PHEV cycles. Here we present results of a single charge sustaining mode cycle. It is worth mentioning that the nominal transient discrepancy between modelled and measured voltages were below 2% during most part of the simulation and in some cases peaked to 5% as shown in Figure 6b (i.e., the maximum transient discrepancy between modelled and measured voltage is less than 5%). The pack was connected to a cooling system passing liquid coolant at a rate of 27L/min thorough the cooling plates attached to the bottom of the pack (opposite end to cell tabs).

**Figure 6a:** A 63 minute current cycle consisting of three phases: The first 24 minute charge depleting phase with currents between  $-200A < I < 130A$  takes the cell from 70% SoC down to 10% SoC; this is followed by a 34 minute phase of constant 40A charge which takes the cell back up to 70% SoC; the final phase is a 5 minute charge depleting phase with similar current magnitudes.

**Figure 6b:** Shows a good fit between modelled voltage (red) and measured voltage (blue). During most of the simulation errors were below 2%, with a peak error of 5% at around the 5000 seconds.

**Figure 6c:** Compares modelled temperature (red line) versus maximum recorded cell temperature in the pack and minimum recorded temperature (blue dashed lines).

## 4 Conclusions

In this paper we present a library of models that extend to construct a coupled, dynamic, electro-thermal model of battery cells and packs. At the elementary level we utilize a single polarization equivalent circuit model (ECM) to capture the Ohmic and diffusional characteristics of a Lithium ion battery. The EC model is then developed to include effects of hysteresis, self-discharge and diffusion limitation.

A distinguishing property of this model is the inclusion of diffusion limitation effects through a current dependant time constant. This property better mimics the solid diffusional dynamics of  $Li^+$  intercalation into the active material.

Employing an optimisation routine we extract state of charge (SoC), temperature (T) and current dependent (IL) model parameters from High Pulse Power Characterization (HPPC) data. This extracted data then forms a three dimensional “look-up table” which is interpolated using Spline functions in the ranges  $0\% \leq SOC \leq 100\%$  and  $-20^\circ C \leq T \leq 65^\circ C$ .

The model (cell, module and pack) is acausal and thus utilises physical pins that mimic battery terminals. Stimuli are therefore any load acting on the battery via the tabs (as is the case in reality) and outputs are any measurements that are made across the tabs (using modelled sensors).

The cell model was validated using a number of commercially available cells. Our combined validation results showed a maximum of 50mV discrepancy between measured and tested voltages at cell level and a  $1.4^\circ C$  discrepancy between measured and tested temperature at cell level.

Our pack model is constructed from a series-parallel configuration of cells where cell-to-cell connections are modelled by a resistor. Our focus for this integrated architecture was methods of automated and unique parameterization which facilitates, for example, the study of the effects of SoC imbalance, anomalous resistances and SoC balancing mechanism.

An important characteristic of the model presented here, which is unique to Modelica code, is that it is based on equations instead of assignment statements. The main advantage is that the solution direction of equations will adapt to the data flow context in which the solution is computed. The nature of the equation based approach means that the models are acausal. This in turn means that the modeler does not have to rewrite or rearrange the system equations when using the components in different scenarios, for example forward and inverse dynamic modelling situations. More advantageously a model of a battery behaves physically like battery. So for example, if a resistor is connected to the physical pins (modelled negative and positive terminals of a battery) the battery will discharge causing a rise in temperature, fall in SOC, fall in voltage and so on.

In this work we demonstrate Dymola's ability for multi domain modelling. We find that the Mdoelica libraries including Electric, Fluid and Thermal readily facilitate the construction of coupled electro-thermal battery models. However, we also find that Dymola is lacking in some areas of numerical problem solving, particularly in solving coupled non-linear simultaneous equations as well as coupled non-linear partial differential equations. We circumvent these problems by employing regression methods for predicting battery parameters.

## Abstract

*The initial integration of a large scale battery system in existing end products like cars is usually of experimental nature. So are the simulation models supporting its design process. In the following a comprehensive Modelica model is introduced for the simulative description of the physical behavior of lithium ion battery cells packs for relevant aspects and use cases. It is part of the Modelon Battery Library, a commercial Modelica library to model battery cells and packs of various types, shape and grouping.*

*Thermal behavior, electrical behavior and the impact of the degradation due to aging are considered as they influence each other.*

*The model parameters to calculate the electrical behavior are to be derived from measurements; an optimization algorithm to obtain them is integrated in the package using the Optimization Library. Functions to validate the model against these measurements are included as well.*

*As an application example the simulation of an energetic energy storage system in the model of a battery electrical vehicle is shown.*

**Keywords:** battery model; lithium-ion; behavioral modeling; electrical vehicle

## 1. Motivation

In Battery Electric Vehicles (BEV) and Hybrid Electric Vehicles (HEV) the majority of car producers focus in lithium ion based battery concepts due to their high performance density in connection with reasonably high lifetime and acceptable thermal behavior. As

these vehicles become more accepted on the market, the production numbers are supposed to increase with some positive pricing effect. It is likely that this will also make lithium ion batteries attractive for use in homes and other decentralized energy systems – especially in connection with renewable energy.

Practically all lithium ion based batteries show more or less troublesome aging behavior which reduces the lifetime to unacceptable levels, if no particular provisions are taken to avoid or reduce it. Aging appears as calendric and as cyclic effect according to the number of charging and re-charging events. The main aging effects [1] of current lithium battery systems are:

- Accumulated damages of the solid electrolyte interface (SEI) between anode and electrolyte caused by chemical reactions and physical movement due to temperature changes.
- So-called lithium plating, i.e. the deposition of metallic lithium on the anode.

Aging effects are severely influenced by the thermal load on the battery. Therefore high performance battery systems need to be kept within a certain temperature range by cooling and sometimes heating.

For whatever application, in current battery systems single cells of a certain type are arranged in stacks, modules or packages through serial and parallel alignment of the cell. Cells can have cylindrical, prismatic or so-called coffee bag shape. Apart from the electrical interconnection, the cells are integrated in some thermal design concept to cool them and reduce aging. It should be noticed that car as well as energy system manufacturers design battery systems according to the

needs of the general concept of their product. I.e. the design of the battery is not based on a unified single-type approach, but many different concepts are required to cover the large range of system requirements.

Fig. 1, Battery system of the MUTE electrical car project by TU Munich

Therefore, the battery model presented in this paper uses the cell as a base unit to be parameterized with fairly simple data sheet and empiric input. With the help of pre-defined templates, organized as shown in figure 1, the user can easily set-up a battery model as an electrical and thermal system consisting of a single cell.

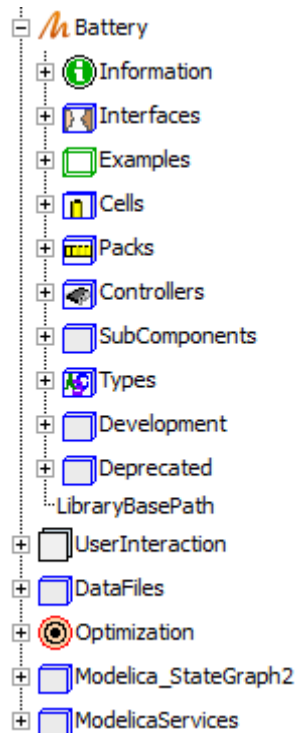

Fig. 2, Content of the Battery Library

Aging information is provided by an integrated aging system or user-defined approach.

While lithium ion battery cells are usually described by RC circuit elements, the electrochemical effects in lead-acid batteries are approximated in a separate model to take account of the specialties of this battery type.

## 2. Electrical Modelling

The main requirement for cell models used in system simulation is to provide accurate information on the macroscopic characteristics (e.g. voltage, current and state of charge) combined with reasonable computation time. In many applications these requirements are fulfilled by models using an electrical equivalent circuit.

The voltage of a battery  $U$  can be described as the difference between the open circuit voltage  $U_{OCV}$  and a number of overpotentials  $\eta_i$  caused by different electrochemical effects:

$$U = U_{OCV} - \sum \eta_i$$

These overpotentials can be modelled with electric networks. In figure 2 the voltage characteristic for the step current discharge of a NiMH cell is shown.

Fig. 3, Voltage characteristic of NiMH cell [1]

The overpotential is divided into an ohmic overpotential  $\eta_{ohm}$ , overpotential caused by charge transfer and the electrical double layer  $\eta_{trans}$  and overpotential due to diffusion  $\eta_{diff}$ . An electrical equivalent circuit capable of reproducing the shown voltage characteristic is shown in figure 3, whereas the dynamic behavior the overpotentials are modelled using RC-circuits.

Fig. 3, Equivalent circuit

The performance of a cell is strongly depends the battery current, state of charge, temperature and other factors. To achieve good performance of the model over a wide range of conditions the consideration of these dependencies in the models of the electrical components and their parameterization is crucial.

The presented library offers equation based and table based modeling of the electrical components. As an example of equation based modeling a lithium ion cell model [2] and a lead acid cell model [3] are implemented in the library. The electrical equivalent circuits of the models contain serial resistors, RC-circuits, voltage sources representing the open circuit voltage and current sources describing the leakage current. The functions representing these elements are derived from measurement data and depend on the temperature, state of charge and current.

The table based models perform a table lookup to determine the parameters of the components in the electrical circuit. The library offers pre-defined templates for 2D and 3D interpolation. They enable a variable composition of elements in the equivalent circuit. In the 2d interpolation template the dependency of the lookup tables can easily be configured.

For the simulation of battery packs containing multiple cells, templates using discretized or scaled cell models are implemented. In the discretized pack models every cell is modeled separately. This enables the analysis of the packs' electrical behavior when unconformities of the included cells occur. As the geometric layout usually doesn't correspond to the electrical connections of the cells in the pack, a connection Matrix  $M$  is defined, that offers the possibility to connect the electric connectors of the cells in a given design.

### 3. Parameter Estimation

When modeling the electrochemical processes in a battery using a simplified approach like an electrical equivalent circuit, the choice of the circuit's components and the parameterization of these components determine the performance of the model.

A widely used approach to parameterize battery models is the generation of lookup tables from measurement data using numerical optimization algorithms ([6], [7]).

As mentioned before the battery performance is strongly dependent on numerous factors. The number of dependencies that are important for the interaction within the investigated system and the size of the range in which they need to be considered often lead to a complex optimization task.

The developed library provides a Dymola internal approach to execute parameter estimations using the commercial library Optimization developed by the German Aerospace Center (DLR) which includes several numerical optimization algorithms [10]. A template of a parameter estimation for an equivalent circuit containing a serial resistor and two RC-circuits generating 2d lookup tables is implemented. The workflow of the template is illustrated in figure 4.

Fig. 4, Parameter estimation workflow

The inputs to the parameter estimation routine are inner resistance measurements from discharging or charging the battery with step currents. For each measurement an optimization function from the Optimization Library is called. The optimization function simulates a model that contains the equivalent circuit and computes the optimization criteria which is returned to the optimization function. The outputs of the parameter estimation are 2D lookup tables for the resistors and the capacitors in the circuit.

When computing the parameters of all components in a single estimation task the generation of plausible lookup tables is a complex

challenge [8]. To simplify this challenge and dictate e.g. which RC-circuit represents the fast dynamics and avoid a switch of assignment during the estimation task, the boundary  $b$  for each parameter can be set by

$$b = k_1 + k_2 \cdot \Delta R^{k_3}$$

$\Delta R$  is the increase of the inner resistance during the measurement and  $k_i$  are constants defining the boundary. This rather simple method showed acceptable results estimating current and state of charge dependent tables for a NiMH cell.

## 4. Thermal Model

In order to determine the influence of varying temperatures on electrical and aging behavior a thermal model of the cell and its surrounding environment is required. Heat inside the cell is generated mainly due to Joule effects, the chemical reactions are only weakly exothermic or even endothermic. Thus the generated heat corresponds to the power loss calculated in the resistors of the equivalent electric circuit which are therefore connected to the thermal model.

### Cell

The thermal model uses a template/interface structure with a replaceable thermal model such that the discretization level can be adapted by the user. All models are based on a finite volume approach, using heat resistors and thermal capacities. The user can choose between 0D and 1D models, further models can be added easily

Conditional heat ports at the top, side and bottom of the cell reduce the complexity without reducing the flexibility of the thermal management design.

Equations for the calculation of thermal parameters are provided for cylindrical and prismatic forms. Material records for the most common materials are also included.

### Packs

In addition to the cell, the thermal model of the pack might consider housing and in case of the discretized pack a filling material in between the cells. Simple heat transfer models for convection and radiation are also included.

For the scaled models, the heat flow of a single instance of the cell is multiplied with total number of cells. Effects such as heat conduction in-between the cells can only be considered in the discretized pack models with several instances of the cell model. Heat transfer via pins can also be modelled; the connections between the pins use the same connection matrix as the electric part.

A two-dimensional heatport simplifies the icon of the housing, Cells, filling, and the exterior heat ports can easily be connected.

The temperature of the pack can be monitored with a provided controller model. Based on given limits. Boolean signals for activation of heating or cooling are emitted.

Fig. 6, Structure of thermal model of a discretized battery pack

## 5. Aging Model

The capacity as well as the behavior of a cell change with age and cycle numbers of the cell. To account for the effects of the most important factors temperature, current rate and SOC, a flexible aging model based on the StateGraph library has been implemented.

The aging factor  $\varphi$  denotes the ratio between the current value and the value at  $t=0$ :

$$\varphi_A = \frac{A(t)}{A(t=0)}$$

Using this definition, the actual value can be determined just by multiplying with  $\varphi$ . Resistor and capacitor models have a conditional input for the aging factor that can be activated in the parameter dialog.

The flow chart in figure 6 shows the signal flow structure in the aging model. The cycle detector detects the end of a cycle and triggers the calculation of the aging factors in the cyclic and calendric aging models. Mean values

for temperature, depth-of-discharge (DOD), voltage and current are calculated for the previous cycle as the aging models are all based on continuous boundary conditions. The aging factors are discrete values, thus they are constant during one cycle until the next calculation is triggered. Therefore, the aging factors represent the age of the cell at the beginning of the next active cycle. Start value for all aging factors is set to 1.

Fig. 7, Flow chart of the aging model mechanism

Both aging models use a semi-empirical approach to determine the aging factor based on recent publications ([4], [5]). The aging models are replaceable and can be switched on/off individually. New aging models can easily be added by using the provided interface.

The aging of cells during storage (calendar aging) is mainly caused by electrolyte decomposition and the growth of the solid electrolyte interface. Ecker et al [5] describe this process with a square root dependency on time. For voltage and temperature, an exponential approach is chosen. The implemented model is based on extensive measurements on 30 NMC cells stored at different SOC and temperatures. The semi-empiric approach allows the user to adopt the parameters to his data even with a low number of measurements. The calendar model calculates aging factors for the cell capacity, the serial resistance and the parameters of the first RC-circuit. Thus, the degradation of capacity as well as the loss of power and changes in the dynamic behavior due to calendar aging can be shown.

It is supposed that the loss of active lithium due to anode degradation is the cause of capacity loss due to cycling of the cell [5]. Wang et al performed measurements with varying time, temperature, depth of discharge and discharge rate. They developed a generalist model for cyclic aging that can be adapted to different Li-Ion chemistries as long as the aging mechanisms are also based on diffusion processes. By using the energy throughput of

the cell as input of the aging factor calculation instead of time, the equation becomes independent of the charge rate. As the experiments showed little influence, the SOC of the cycled cell is neglected.

Figure 7 shows the aging factors for a cell cycled with a constant current rate between 0.5 and 0.55 SOC at 20°C. The aging factors for capacities decrease, those for the resistance increase, both reducing the capacity as well as the power of the cell.

Fig. 8, Aging factors for cycling a cell between 0.5 and 0.55 SOC with 0.5C-Rate at 20°C

## 6. Application Example

Fig. 9, Battery Lib within a Catia V6 Systems model of an e-car

In order to demonstrate the application of the Battery Library within a vehicle environment, an example project has been created based on the “Light Car” – a battery electric vehicle concept designed by the company EDAG. The development methods applied were chosen to

replicate the real-world methods as closely as possible. The partners participating in the project are the companies EDAG (to represent the car development competence), Transcat (to represent Catia V6) and Modelon (to represent system simulation with Modelica). Dimensioning the battery in terms of vehicle autonomy and its aging behavior are also in the scope of the project as well as the first time application of state-of-the-art development tools. In order to realize typical driving scenarios and test cycles like NEDC the system simulation model consists of a longitudinal dynamic vehicle model, the driving resistances and a driver. The focus of the model lies on the battery system, including its electrical, thermal and aging behavior and the battery controller.

In current e-car projects, the battery cells are supplied by cell manufacturers, but combined to a battery system at the OEM car producer. The control of the battery's primary states such as current, cell temperature, state of charge and state of health has to be in line with the entire car concept and is therefore OEM work, too. The key design factors of the battery system are the arrangement of the cells in stacks and packs under maximum utilization of their potential in terms of performance and duration of life. In this context, due to the very high influence of the temperature on the aging, certain limits have to be kept during all conditions of operation. In the presented project, the cooling design is based on air flow. For a maximum precision of the calculations, the 1D system simulation results from the Modelica / Catia V6 Systems environment have been verified using a finite element simulation in the tool Simulia.

A typical simulation result in terms of a cell temperature is shown in Fig. 9.

Fig. 10, Temperature (red) and heat performance (blue) of a battery cell within the NEDC drive cycle

## 7. Summary and Outlook

The battery model of Modelon's Battery Library for Lithium Ion cells has been described in its structure, functionality and employment.

The calculation of the electrical behavior by equivalent circuit models with table based and equation based approaches has been shown as well as its parameterization function based on the Optimization Library. The thermal model has been described for single battery cells and battery packs. The estimation of degradation due to cell aging has been modelled in different ways, calendric aging and cyclical aging. An example for the integration of the battery model in a vehicle simulation of an electrical car has been described in the "Light Car" project.

The Battery Library was designed with the intention to be coupled with other system models in Modelica-based or other simulation frameworks. As the battery model features all necessary interfaces, the code of a battery management system in a signal flow simulation environment can be attached as an FMU. Vice versa, it is possible to use this physical battery model for the prediction of the thermal-electrical behavior as well as aging on a battery management system or for a "model in the loop" approach.

The ongoing development of the Battery Library is heading towards electrochemical modelling of the aging behavior by the implementation of a "Dual-Foil-Model" [9] and the advancement in the thermal modelling of large electrical energy storage systems comprising several battery packs. Introduction of models for capacitors of the "super capacitor" type is also planned.

## Abstract

*This paper introduces behavioral (macro) models of power semiconductors, i.e. diodes, MOSFETs and IGBTs, being part of a library for simulating power electronics utilized, e.g. in electrified powertrains of either hybrid electric vehicles (HEV) or purely battery electric vehicles (BEV). The models consider static, dynamic (switching mode) and thermal effects and in most cases can be fully parameterized solely on the basis of characteristic curves and parameters specified in datasheets. The main purpose of behavioral models is an accurate representation of the semiconductor signals to, e.g. calculate the overall losses. The MOSFET models are verified in simulations with various test circuits and are validated with measurement data provided by a company developing electric drive systems. Furthermore, the arising numerical problems are discussed and possible solutions are provided on how to modify the models in order to use them in e.g. system simulation.*

**Keywords:** power electronics, power semiconductors, macro modeling, behavioral modeling, numerical performance

## 1 Introduction

In practice, models of electric powertrains - consisting of at least a high-voltage battery, an inverter and an electric machine - have to answer questions regarding lifetime, maximum driving range, temperature development or overall efficiency. One of the most important and challenging tasks is to provide models that can be parameterized easily and simulated fast and robust, i.e. numerically stable.

Models of power electronic components are available in different degrees of complexity in freely- and commercially distributed libraries. When needed for industrial use, ideal models are often not accurate

enough, whereas physical ones cannot be parameterized with standard datasheets and are rather suited for the field of research. Moreover, such models are often solely available in a specific level of detail which either results in unreasonable simulation times in case of very detailed models or a lack of information in case of e.g. ideal models. In [6] different modeling techniques of the switch models available in the Modelica Standard Library (MSL) are discussed.

A trade-off between these ideal and micro modeling techniques is a macro modeling approach called *behavioral modeling*, which was first introduced for power semiconductors in [8] and is further developed at Modelon GmbH. The idea of this technique is to describe the component's behavior via characteristic curves and parameters provided in datasheets. Thus, on the one hand behavioral models of MOSFETs can be parameterized solely on the basis of datasheets and on the other hand, the models behave as specified by the manufacturer under nominal conditions. In case of IGBTs due to their internal semiconductor structure, the occurring tail current has to be measured in advance. Moreover, in trench/field-stop IGBTs due to the additional field-stop layer added to the semiconductor structure the model developed in [8] is not valid anymore and has to be modified.

Since behavioral models provide detailed switching slopes, the simulation performance is totally unacceptable if such models are used to simulate, e.g. the driving range of an electric vehicle. Hence, some possibilities are discussed on how to use such models to derive table based models that store solely the information needed for a specific simulation task.

## 2 Behavioral Modeling of Diodes

In the Modelica Standard Library (MSL) several different models of diodes are available (refer to [6]). The ideal diodes are modeled using parameterized curve descriptions, whereas the physical ones are described

by the well-known Shockley equation. These models are perfectly suited for, e.g. circuit analysis. However, if conduction- and switching losses of a specific diode are of interest none of these models can be used since they neither include the appropriate equations describing the transient (switching) behavior nor cannot be parameterized using datasheets. Behavioral models provide the means to make use of datasheet values to model the static- and dynamic behavior.

## 2.1 Static Model

In the simplest case, the static model of a diode can be described as depicted in Figure 1. The current through the diode is measured using a current sensor and serves as input signal to a table which stores the forward characteristic  $V_f = f(I_f)$  specified in the datasheet. The corresponding forward voltage drop is fed into a signal-controlled voltage source. The additional ideal reverse blocking diode ensures that the current solely flows in forward direction.

Figure 1: Static model of a diode:  $V_f = f(I_f)$

Usually datasheets provide the diode's forward characteristic not only as a function of the forward current  $I_f$  but also of the temperature  $T$ . Hence, the model has to be modified as depicted in Figure 2.

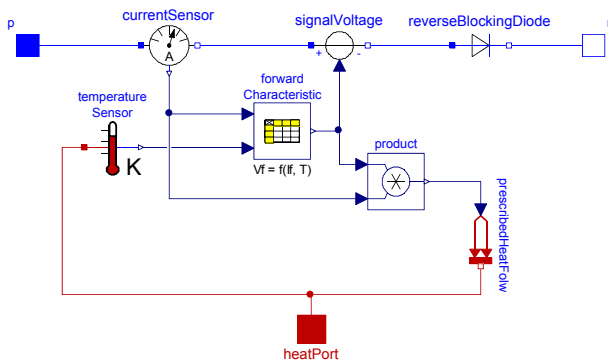

Figure 2: Static model of a diode:  $V_f = f(I_f, T)$

The losses generated while the diode is conducting are nothing else but a thermal heat flow which will result in a certain temperature depending on the thermal network connected to the heat port.

## 2.2 Dynamic Model (Reverse Recovery Effect)

The dynamics of a diode occur due to its junction- and diffusion-capacitance. An approach of modeling these capacitances is given in [8]. The main problem is that the capacitance values depend on parameters that are not available in standard datasheets. As the dynamics of a diode in terms of switching losses are mainly dependent on the *reverse recovery effect*, an approach has been followed which was published in [3].

## 3 Behavioral Modeling of Power-MOSFETs

In order to understand the behavioral model of a power-MOSFET its structure will be discussed briefly. After introducing the models its modes of operation will be verified using different test circuits. Finally, the model is validated with measurement results provided by a company.

### 3.1 Power-MOSFET Structure and its Modes of Operation

By means of the MOSFET's semiconductor structure, the different modes of operation shall now be analyzed. Based on that, a static model can be developed. In Figure 3, the structure of a vertical power-MOSFET is illustrated.

Figure 3: Structure of a power-MOSFET

It is first supposed that a positive gate-source voltage is applied, i.e. a conducting channel between drain and source arises. Now, the MOSFET operates in on-state. Thus, if a positive drain-source voltage is applied (on-state forward conduction mode),

current flows from drain to source, which represents the MOSFET's first quadrant operation. Since the conducting channel is not a pn-junction but more of a voltage-controlled resistance, current can also flow from source to drain if a negative drain-source voltage is applied (on-state reverse conduction). This was not considered in the model developed in [8] and will be added to the model demonstrated in this paper. In the modified version of the MOSFET, the characteristic curves in the first quadrant are mirrored into the third quadrant. The only difference in third quadrant application is an additional parasitic diode - the *body diode* - between drain and source. If the current in reverse direction is high enough to cause a voltage drop equal to the body diode's threshold voltage, the body diode starts conducting and provides an additional current path. A more detailed description of these reverse conduction modes can be found in [9, p. 61 ff.]. In order to analyze the off-state modes, the gate-source voltage is supposed to be zero meaning that the conduction channel does not arise. Still, the body diode can conduct current in reverse direction. In forward direction, no current can flow. In summary, the discussed modes of operation are listed below.

- Mode 1:* on-state forward conduction
- Mode 2:* on-state reverse conduction
- Mode 3:* on-state reverse conduction with body diode forward biased
- Mode 4:* off-state reverse conduction
- Mode 5:* off-state forward blocking

### 3.2 Power-MOSFET Model

Based on the modes of operation, a behavioral model of the power-MOSFET is developed in the following. First, a static model is derived, which afterwards is extended to cover dynamics and temperature dependency.

#### 3.2.1 Static Model

In order to describe the static behavior of a MOSFET, the modes of operation discussed before have to be realized in a model structure. As depicted in Figure 4, the transfer behavior and therefore the MOS-structure is modeled by a voltage sensor measuring the applied gate-source voltage. This voltage signal is the input to a table which stores the transfer characteristic  $I_d = f(V_{gs})$  specified in the datasheet. The table's output is the maximum current, which can flow due to the

applied gate-source voltage. This current value is the input to the signal-controlled current sources. Since the current that flows through the component is determined by the external load circuit, e.g. by an inductive load, each current source has an ideal diode in parallel ensuring that the current that is not drawn by the load can free-wheel through these diodes. In Figure 4 the current paths in the different modes of operation are marked with arrows. In mode 1, the current flows through the resistor  $R_{onFw}$ , which represents the conducting channel. Another ideal diode is connected in series which ensures that the current solely can flow from drain to source. In the second mode, the current flows through the resistor  $R_{onBw}$  and again, an ideal reverse blocking diode ensures that the current flows in the right direction. The body diode provides the current path for the third and the fourth mode. If the MOSFET is in on-state, the current will split between the reverse leg and the body diode as soon as the body diode's threshold voltage  $V_f$  is reached. In off-state, the MOSFET is a simple diode conducting in reverse direction and blocking in forward direction.

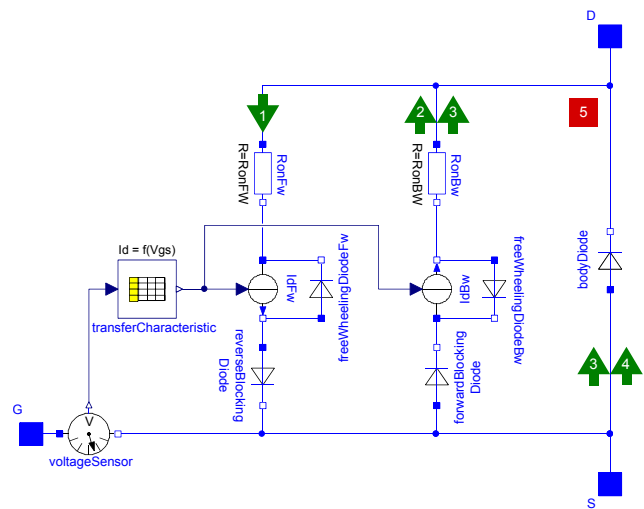

Figure 4: Static model of a power-MOSFET

#### 3.2.2 Dynamic Model

For solving a demanding simulation task, a static model is often not sufficient enough. Especially when switching losses are of interest, a dynamic model is indispensable. The static model shall now be extended to introduce the component's dynamics, which are mainly an effect of capacitances between the MOSFET's connections. As the manufacturers do not provide these directly but in form of the input capacitance  $C_{iss}$ , the output capacitance  $C_{oss}$  and the reverse trans-

fer capacitance  $C_{rss}$ , the following conversions have to be made to gain the effective capacitances between gate, drain and source:

$$C_{ds} = C_{iss} - C_{rss}$$

$$C_{gd} = C_{rss}$$

$$C_{gs} = C_{oss} - C_{rss}$$

These equations are computed in the *capTable* block, which can be seen in the dynamic model in Figure 5. The characteristic curves  $C_{iss} = f(V_{gs})$ ,  $C_{oss} = f(V_{gs})$  and  $C_{rss} = f(V_{gs})$ , specified in the datasheet are stored inside tables. The computed values are the inputs to the signal-controlled capacitors, which can be seen in the model. The MOS-structure is modeled with an RC-circuit. The gate-source capacitor is charged through the internal gate resistor and the gate-source voltage is the voltage across the capacitor.

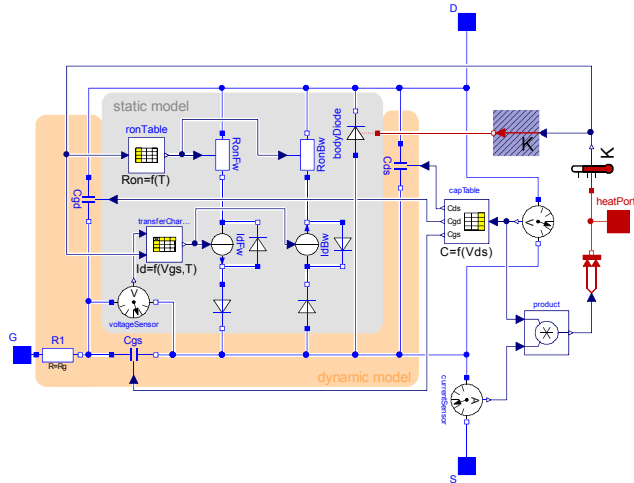

Figure 5: Dynamic model of a power-MOSFET

### 3.2.3 Temperature Dependency

Besides dynamics, temperature dependency is introduced to the model in Figure 5. Thus, in the transfer characteristic table a second input was introduced, i.e.  $I_d = f(V_{gs}, T)$ . The constant resistors have been replaced and are controlled by the characteristic curve  $r_{on} = f(T)$ . The body diode model was extended such that it considers temperature in the diode's forward characteristic table  $V_f = f(I_f, T)$  and that switching losses can be computed, i.e. the reverse recovery effect was modeled according to [3]. The total power losses are computed by multiplying the drain-source current and voltage and forwarded as heat flow to the heat port. This enables the use of a thermal network to compute the device's junction temperature.

### 3.3 MOSFET Model Verification

In order to verify the behavior of the static model in Figure 4, two test circuits have been created. For verifying modes 1, 2, 4 and 5, the circuit in Figure 6 is used. In order to test the on-state modes, the gate-source voltage is set to 10V; for testing the off-state modes it is set to 0V. The constant supply voltage source is either positive or negative depending on whether a forward conduction mode or a reverse conduction mode is tested. With the chosen load resistance, a current of approximately 100A will be drawn.

Figure 6: Test circuit for modes 1, 2, 4 and 5

Figure 7 shows the simulation results of the test circuit. It can be seen that in mode 1, the total current flows in forward direction through the resistor *RonFw*. In mode 2, the input voltage is set negative and therefore the total current flows in the backward branch through the resistor *RonBw*. In the diagram of the fourth mode, it is shown that the current is neither flowing through *RonFw* nor through *RonBw* but through the body diode. The last diagram proves that no current at all flows in mode 5.

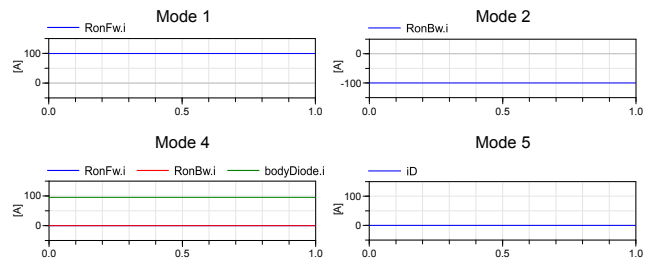

Figure 7: Simulation results for modes 1, 2, 4 and 5

To test the third static mode, the test circuit has been adapted in the way it is shown in Figure 8. The constant supply voltage source has been replaced by a signal-controlled voltage source with a ramp input. This causes the input voltage and therefore the current to increase linearly.

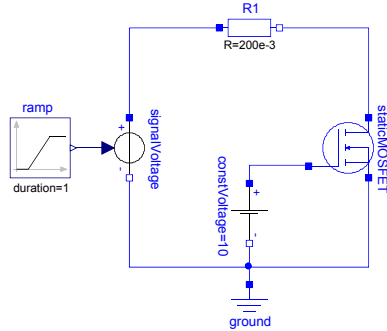

Figure 8: Test circuit for mode 3

Figure 9 shows the simulation result. The input voltage decreases from  $-20V$  to  $-50V$ . At the beginning, the current flows in the backward branch through the resistor  $R_{onBw}$ . At an input voltage level of about  $-31V$ , the current through this resistor produces a voltage drop equal to the diode's threshold voltage. Hence, the diode starts conducting and builds a current divider together with  $R_{onBw}$ . The total current is then divided into the two branches. The green curve represents the sum of the two branch currents, which is the total linearly decreasing current.

Figure 9: Simulation result for mode 3

The test circuit in Figure 10 is used to verify the MOSFET's dynamic behavior. The device is alternately turned on and off by the pulse voltage pattern applied between gate and source. A constant junction temperature is assumed and applied externally.

Figure 10: Test circuit dynamic behavior

Figure 11 depicts the simulation results. In the up-

per diagram, one can see the drain current, the drain-source voltage and the power losses of the MOSFET. One can see the conduction losses and the turn-on and turn-off peaks whenever the device is switched. In the lower diagram, the switch-on behavior is shown more detailed.

Figure 11: Switching waveforms and power losses

### 3.4 MOSFET Model Validation

The developed power-MOSFET model was validated with measurement data provided by a company producing electric drive systems. The data was obtained by measurements of a three-phase inverter of one of the company's drive systems. The circuit diagram of this inverter is shown in Figure 12. The device under test (DUT) is an Infineon IPB180N06S4-H1 power-MOSFET. Per phase leg, there are three high- and three low-side MOSFETs to be able to drive the desired load current. The company provided two space-vector modulation switching patterns for two different operating points of the electric machine and the corresponding power losses occurring per MOSFET. The data can be seen in Table 1:

Table 1: Operating points and loss power

	RPM	Torque	Power
Operating point 1	3700rpm	3Nm	1.1W
Operating point 2	700rpm	3Nm	0.9W

Since a synchronous machine with three pole pairs is connected to the inverter, a mechanical revolution speed of 3700rpm results in an electrical frequency of 185Hz. In order to simulate the MOSFET's total power losses correctly, they have to be averaged over this frequency. The resistive-inductive load representing the electric machine, was parameterized in such a way that the measured current for the appropriate operating point is drawn. The three phase currents and the

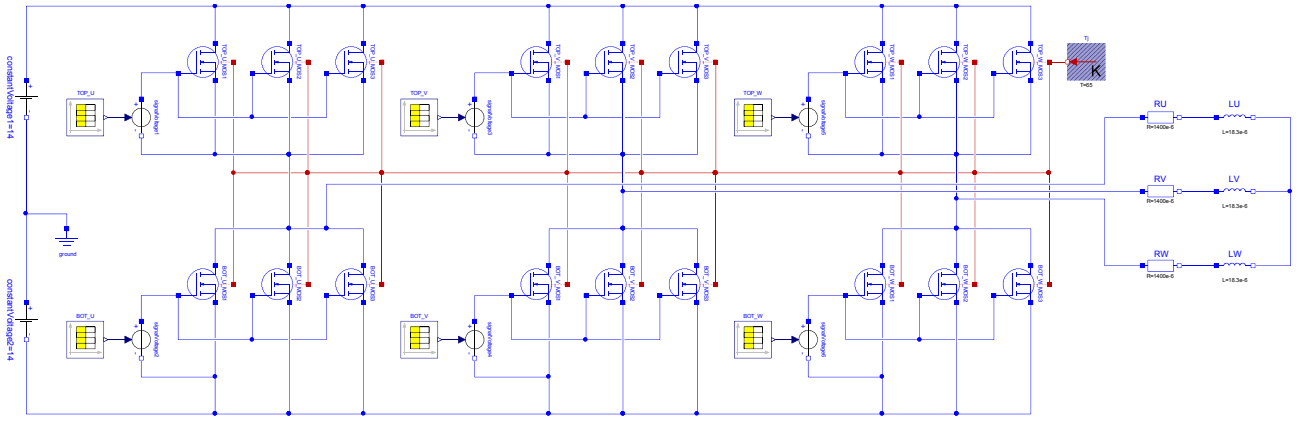

Figure 12: Power-MOSFET based three-phase inverter for driving an electric machine

average power losses per MOSFET are shown in Figure 13. The two curves in the lower diagram represent the power losses of a high- and a low-side MOSFET of the U-phase. The first average value can be computed after one period. It can be seen that once the U-phase current (blue signal in the upper plot) reaches steady-state, the average power losses over one period settle down at  $1.12W$ .

Figure 13: Simulation results of operating point 1

Figure 14 depicts the simulation results of the second operating point. At  $700rpm$ , the inverter's output frequency is  $35Hz$ . Again, one can see the average power losses per MOSFET settle down in steady-state at  $0.91W$ .

Figure 14: Simulation results of operating point 2

The relative error between the measured data and the simulation result lies within 2% in both operating points. These results speak especially for the behavioral modeling technique as well as for the accuracy of the provided information in the datasheets.

## 4 Behavioral Modeling of IGBTs

### 4.1 IGBT Structure and its Modes of Operation

Concerning the IGBT technology, two different design principles are available, NPT- (non-punch through) and PT- (punch through) IGBTs. The basic structure of an NPT-IGBT is illustrated in Figure 15.

Contrary to power-MOSFETs, NPT-IGBTs have an additional p+ doped layer between emitter and collector. This means that the forward characteristic of such a device does not behave like a classic resistance but more like a pn-junction. This pn-junction basically determines the IGBT's behavior in its forward and reverse mode.

Figure 15: Structure of a non-punch through IGBT

If an additional n+ doped layer is introduced between the p+ doped layer at the bottom and the n-doped layer, a PT structure is realized. Due to the additional n+ doped layer the shape of the electric field gets steeper which in turn allows for a smaller n- doped layer, i.e. reduces the chip size (refer to [7] for a more detailed description).

## 4.2 IGBT Models

A static and a dynamic behavioral model of an IGBT is introduced within this section, whereas the dynamic model is different for the NPT- and the PT-IGBT. The verification of the models is similar to the one of the MOSFET and is therefore not discussed in the paper. The validation of the models is currently under development.

### 4.2.1 Static Model

Figure 16 shows the static model of an IGBT. The output characteristic is modeled the same way as the diode's forward characteristic illustrated in Figure 1, i.e. the collector-emitter current is measured with a current sensor and fed into the table providing the IGBT's output characteristic  $V_{CE} = f(I_C)$ . The table's output is then fed into the signal-controlled voltage source. The transfer characteristic is modeled analogously to the MOSFET: The gate-emitter voltage is measured and the maximum current - provided by the transfer characteristic curve which is stored in a table - flows through the signal-controlled current source, i.e. it again behaves like a voltage controlled current source. As for the MOSFET model, a free-wheeling diode provides a path for the current which is supplied too much and a blocking diode ensures that the IGBT is not conducting in reverse direction.

### 4.2.2 Dynamic NPT- and PT-IGBT Model

To introduce dynamics to the model, three capacitors are introduced to the static model discussed before. The gate-emitter capacitor can be approximated as constant over the collector-emitter voltage (refer to Equation 1). The gate-collector capacitor - also known as *Miller-Capacitance* - strongly depends on the collector emitter voltage and can be approximated with Equation 2 [1, p. 15]. The input capacitor  $C_{iss}$  and the reverse transfer capacitor  $C_{res}$  can be found in the datasheet.

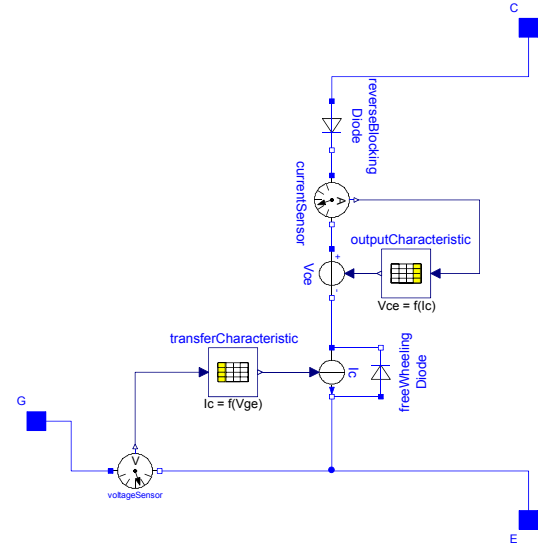

Figure 16: Static IGBT model

$$C_{ge}(V_{ce}) \approx C_{iss}(25V) - C_{rss}(25V) \quad (1)$$

$$C_{gc}(V_{ce}) \approx \frac{C_{rss}(25V) \cdot \sqrt{25V}}{\sqrt{V_{ce}}} \quad (2)$$

Where for instance  $C_{iss}(25V)$  and  $C_{rss}(25V)$  have been determined at a constant collector-emitter voltage of 25V.

Due to the internal semiconductor structure of PT-IGBTs an additional output capacitor  $C_q = f(V_{CE})$  appears which is mainly responsible for the PT-IGBTs switching-off behavior (refer to [4]).

In Figure 17 the dynamic IGBT model is shown. The gate-emitter capacitor is charged over the internal gate resistance  $R1$ . Equation 1 is implemented directly in the parameter window of  $C_{ge}$  as  $C_{iss}$  and  $C_{res}$  are input parameters to the model. Equation 2 is either implemented via equations or a table based model, i.e. the characteristic curve is derived by the equation. Again, temperature dependency has to be introduced to the model (shown for the output characteristic in Figure 17) and the power losses are forwarded as heat flow (not included in the model shown in Figure 17) to the heat port to allow the use of a thermal network.

The main problem of IGBT behavioral models is the lack of information in datasheets regarding tail current. Hence, the tail current has to be measured in advance and fed into the model. Alternatively, if there is no possibility to measure the tail current, the dynamic model can be replaced by the characteristic curves of the switching losses  $E_{on}, E_{off} = f(I_C, T)$ .

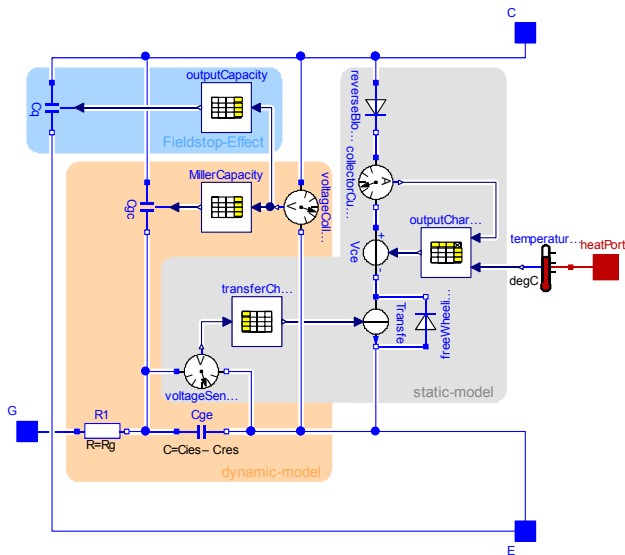

Figure 17: Dynamic PT-IGBT model. If the part highlighted in blue is removed, the model behaves like an NPT-IGBT

## 5 Numerical Performance

The simulation of power semiconductor components faces solvers with a whole series of challenges. To make statements about numerical stability and simulation time, the power-MOSFET model was tested in the three-phase inverter circuit in Figure 12 on its numerical performance<sup>1</sup>.

### 5.1 Integration Algorithm

Detailed modeling of switching operations usually results in so-called *stiff* systems, consisting of differential algebraic equations (DAE) having time constants that differ by several orders of magnitude, e.g. fast switching dynamics and slow thermal processes. These characteristics restrict the selection of the solver enormously. Only solvers based on implicit integration algorithms are suited for such simulations tasks.

Furthermore, switching operations lead to discontinuities in the simulation. Thereby it is distinguished between time- and state-events. In particular the latter causes the solver to iterate for the event, e.g. by using bi-section or regula-falsi algorithms, which increase the simulation time drastically. Even when using an implicit solver, it is not guaranteed that the iterations converge and the simulation succeeds. A deeper insight into this matter is given in [2]. Moreover, if the

<sup>1</sup>any performance comparison was done on an Intel Core i5-3427U CPU, 1.8GHz, 8 GB RAM running Windows 8 (64Bit) and Dymola 2014

switching slopes are not treated ideally, the simulation performance becomes even worse, e.g. real switching slopes are in the region of several 100ns.

### 5.2 Solver Settings

In the upper part of Listing 1, default settings are given which basically match the Dymola standard settings except that the number of intervals is increased due to accuracy reasons. The simulation's performance results, which can be seen in the lower section of the listing, serve as reference values for any following comparison. The impact of the solver settings on the numerical performance is investigated on the basis of the number of function-, hessian- and jacobian-evaluations. At this point it should be mentioned that the parameter for CPU integration time has to be interpreted with caution since it strongly depends on the utilization of the CPU and is therefore not precise in terms of repeatability.

Solver	: DASSL
Number of intervals	: 5.000
Tolerance	: 1e-4
Equidistant time grid	: ON
Store variables at events	: ON
-----	
CPU-time for integration	: 253s
Number of GRID points	: 5.001
Number of F-evaluations	: 1.733.187
Number of H-evaluations	: 292.055
Number of J-evaluations	: 145.405
Number of time events	: 9.988
Number of state events	: 5.401

Listing 1: Default solver settings

First, the influence of the number of points plotted into the output diagram is investigated. If the equidistant time grid is deactivated<sup>2</sup>, the solver does not plot the computed values according to the number of intervals parameter, but instead it plots the entire computed values in the output diagram. The number of grid points then increases drastically (228.795) as it was expected whereas the number of F-, H- and J-evaluations basically stay the same. Nevertheless, the number of points that have to be plotted into the output diagram have a big influence on simulation time.

Next, the impact of the solver's integration tolerance is tested. In order to do this, the tolerance is increased by a power of ten. Due to less F-, H- and

<sup>2</sup>simulation setup - output tab - output selection

J-evaluations, the simulation time could be decreased by approximately 25% but again resulting in a loss of accuracy. The same applies to the option 'store variables at events'<sup>3</sup> when deactivated.

In summary, choosing the solver settings in order to optimize the simulation time strongly depends on how accurate the results shall be. The number of intervals should be chosen manually meaning that the equidistant time grid is activated.

### 5.3 Optimization of the Model

For optimizations of the model, first the ideal components are investigated. The model contains four ideal diodes. The on-resistance and off-conductance is set to  $10^{-5}\Omega$  and  $10^{-5}S$  by default. These values were changed to  $10^{-7}$  for the next simulation. The results showed that this can be done without any problems regarding the simulation speed. A few more state events were generated because the system got stiffer. As a matter of fact, the smaller these values are chosen, the more accurate the power loss computation will be.

Also the tables have optimization potential because the interpolation-type influences the simulation performance. The user can choose between linear and continuous interpolation methods, whereas the first method decreases the simulation time slightly and at the same time is holding the number of additional events (due to the non-continuous method) in a negligible range.

Furthermore, the interpolations can be minimized by fitting polynomial functions through the characteristic curves stored in the tables. The challenge hereby is fitting the curves accurately while the order of the polynomial functions is held low. The problem with higher order polynomials is that they drift away drastically outside the fitted range and in terms of decreasing simulation time the opposite effect would occur. An approach hereby could be to split the curve in multiple sections and fit each with a separate polynomial function. When doing this, a polynomial of higher order can be split into multiple polynomials of lower order resulting in an invariant accuracy and a decrease of simulation time.

### 5.4 Generating Table-Based Models for System Simulation

Although the simulation performance can be slightly improved, the models cannot be used in a system sim-

ulation, e.g. to answer questions regarding temperature development or maximum driving range. For this purpose table-based models (efficiency maps) have to be provided, i.e. the overall losses at several operating points have to be stored in a table. Such models were already developed and verified for electric machines at Modelon GmbH and are currently developed for inverter models.

## 6 Problems with Behavioral Models

Among the bad numerical performance due to detailed description of the signals several other problems occur.

1. Firstly, datasheets provide values derived under nominal conditions. However, when such models are integrated in an electric powertrain the conditions strongly depend on the topology and are usually not as specified in the datasheet.
2. Secondly, values for parasitics elements are only available in datasheets of modules, e.g. inverter modules developed by the semiconductor manufacturer. The parasitics that occur in a specific layout have to be measured and afterwards integrated in the model (by introducing parasitic resistors, inductors and capacitors) to ensure that the switching behavior is modeled correctly.
3. Moreover, in case of IGBT models neither informations regarding tail current nor the output capacitor that appears in the PT structure are provided.

## 7 Acknowledgments

The models have been developed by our former student - Patrick Denz - during his thesis at Modelon GmbH. Especially the MOSFET model was modified by Patrick such that it covers all modes of operation. Many thanks for the great job at Modelon GmbH. Many thanks to Arendt Wintrich for the great support regarding state-of-the-art IGBT models.

## 8 Conclusion

The presented model of a power-MOSFET covers the static as well as the dynamic behavior of the component. Furthermore, it can be parameterized solely on the basis of characteristic curves and parameters specified in datasheets. The verification in various test circuits delivered reasonable results in static and dynamic

<sup>3</sup>simulation setup - output tab - output selection

applications. The model was validated with measurement data of a three-phase inverter motor drive system and the maximum relative error between the measured and simulated total power losses lies within 2%.

Since behavioral models of power electronic components produce many events, the simulation becomes slow. It can be accelerated by widening up the integration tolerance, decreasing the number of intervals or not storing variables at events. Also optimizations on the model itself lead to a better simulation performance. However, when integrating the model into a simulation of the entire vehicle, it must be transformed into an efficiency map model which stores the power losses of different operating points in a table.

The IGBT models are way more complex since the tail current has to be measured in advance to model the signals correctly. If it is not possible - for whatever reason - to measure the tail current it is recommended to replace the dynamic model with tables storing the particular switching losses. This in turn increases the simulation performance and ensures that the losses are modeled correctly.

## Abstract

Modelica models are typically used for simulation to investigate properties of a possible system designs. This is often done manually or combined with optimization to select the best design parameters.

It is desirable to have systematic and partly automated support for exploration of the design space of possible designs and verifying their properties vs. requirements. The META design tool chain is being developed to support this goal. It provides an integration framework for components, designs, design spaces, requirements, and test benches, as well as verification of requirements for the generated design models during design exploration

This paper gives an overview of the META tools and their integration with OpenModelica. The integrated environment currently has four main uses of OpenModelica: importing Modelica models into the META tool model structure, performing simulations within test benches, analyzing Modelica models and automatically adding fault modes, and extracting equations (DAEs) for formal verification tools, e.g. the QRM using qualitative reasoning.

A prototype of the integrated tool framework is in operation, being able to generate and simulate thousands of designs in an automated manner.

*Keywords: Modelica, simulation, design exploration, verification, etc.*

## 1 Introduction

A design tool chain (META tools, Figure 1) is being developed for exploring design alternatives under cer-

tain condition and to verify their properties versus formalized requirements.

A design is built from component model building blocks defining component dynamic behavior and is defined as a composition of component models. A design space can represent different component alternatives as well as different design architectures.

After a design or design space has been created, test cases can be defined against the given requirement set. The test cases, which are called *test benches*, are executable versions of the system requirements.

From the test bench models, the META tools can compose analysis packages over a design space for different domains such as simulation of DAEs (differential algebraic equations), formal verification, static analysis, and structural analysis.

The integrated environment currently has four main uses of OpenModelica: importing Modelica models into the META tool model structure, performing simulations within test benches, analyzing Modelica models and automatically adding fault modes, and extracting equations (DAEs) needed for formal verification tools.

## 2 The OpenMETA Tool Chain

The OpenMETA<sup>1</sup> tool chain is being developed under DARPA's Adaptive Vehicle Make (AVM) [5] program that contains a set of projects one of them is the META project. The AVM program aims to reduce vehicle design and manufacturing time using the framework and toolset provided by the META program.

---

<sup>1</sup> Provided under MIT license

Figure 1. Design flow in the OpenMETA Tool Chain.

The tool chain consists of a language/meta-model called Cyber Physical Modeling Language (*CyPhyML*), a set of *model transformation software* components that translate from *CyPhyML* models to various domain tools, an analysis package executor (referred to as *Job Manager*), and a visualizer (referred to as *Project Analyzer*) for inspecting and understanding the results of analysis packages.

We present (a) the concepts defined in *CyPhyML* in Section 2.1, (b) the integration points with and utilization of OpenModelica in Section 2.2 and Section 2.3, (c) collected analysis results in Section 2.4 and Section 2.5, and (d) the usage of formal verification methods in Section 2.6.

## 2.1 Concepts

*CyPhyML* is a Domain Specific Modeling Language (DSML) built for modeling cyber, physical, and manufacturing component models, composing the component models, making architecture trade-offs using design spaces, and encoding test cases for various analysis domain tools. *CyPhyML* is defined using the MetaGME language in the Generic Modeling Environment (GME [6]).

A *CyPhyML* Component model contains interfaces (physical, structural, and data) of a physical entity or a controller, key parameters of the component, and the relationship between component level parameters and domain model parameters. For instance, a mass component can have a *manufacturing domain model*, a *geometric domain model* (CAD), and a *behavior domain model* (Modelica model).

The component model level parameters can affect all domain model parameters at the same time, i.e., if the mass has dimension and density parameters, then the CAD model and the behavior model are parameterized with exactly the same values respecting unit conversions.

When the CAD and behavior models are composed, all parameters will be consistent across all domain models. *CyPhy* Component models do not contain any internal details of the domain models; they capture information only about interfaces and links to the domain models.

A *CyPhy Component Assembly model* can contain any number of *CyPhyML* Components and other *CyPhyML* Component Assemblies, which together provide system and subsystem concepts. This language feature makes hierarchical composition possible through interfaces (ports and parameters). A full system model is often called a point design or a single design configuration.

A *CyPhyML Design Space model* can encode multiple design configurations (i.e., component assemblies) by using alternative and optional containers inside the design space. Design space models generate a discrete design space in the form of design configurations using the Design Space Exploration Tool (DESERT [5]).

For instance, if the design space contains a mass component, alternative mass components can be added (e.g. using different geometric sizes, material, etc.); if 3 options are added for the mass component, the design space will grow to 3 design configurations. If we have a mass, spring, and damper system (similar to a very simplified suspension assembly) and 3 options are

available for each, then the overall design space would be 27 configurations.

To solve the design space exploration problem, CyPhyML supports design space constraints that can be expressed as auto-generated range constraints, property constraints (e.g. component level parameter limits), visual constraints (e.g. compatibility between components/material or symmetry), or as Object Constraint Language (OCL) constraints. Constraints are used to prune the exponentially large combinatorial design space to a feasible and manageable set of configurations.

Once a CyPhyML Design or Design Space is built, we can define the evaluation of designs using CyPhyML Test Bench models. CyPhyML Test Benches are used to set up boundary and environmental conditions for designs in which they should be evaluated. Test benches also provide sufficient information and any additional models (e.g. stimulus, load, external ‘test’ components) to the system to make simulation and analysis possible with a domain-specific tool.

CyPhyML supports various types of test benches, including Dynamics (i.e., Modelica simulations), formal verification, CAD (e.g. composing the 3D model and computing center of gravity or mass), finite element analysis, computational fluid dynamics, blast, ballistic, conceptual manufacturing, detailed manufacturing, and reliability analysis.

In this paper we focus on *formal verification* and Dynamics (Modelica) *simulation test benches* only. CyPhyML Test benches contain a top level system under test (design or design space), input parameters that can change environment, load, stimulus conditions (test component parameters), and outputs called metrics.

## 2.2 Importing Modelica Models

CyPhyML Components have associated behavior models in the form of linked Modelica models. Only Modelica parameters and Modelica connectors need to be represented in the CyPhyML Component model. The behavioral model aspect of a CyPhyML Component can be viewed as a lightweight wrapper around a Modelica model, which can be built using the OpenMETA tool set and its editor GME.

Building the Modelica model interface representation in GME can be cumbersome and a time consuming activity. All information about the interface exists in the Modelica model, already including the following: model name, model type, connector names, connector types, parameter values (e.g. default value, minimum value, and maximum value), and class restrictions.

The user has to provide a set of Modelica models in textual form (.mo files or one .mo package). A wide set

of Modelica models can be imported in an automated way as CyPhyML Components or CyPhyML Test Components using the OpenModelica Compiler (OMC) API. There is a seamless integration between the OpenMETA tools and the OMC API. The OMC API provides functionality to load model files and libraries (i.e., packages), query containment and inheritance relationship between types, and navigate through model elements using the abstract syntax tree.

The Modelica model importer has certain limitations and it does not support the entire Modelica language. Conditional ports and parameters, enumerated types, and parameterized ports (which can change their internal structure) are not supported. ‘Replaceable’ elements have a limited support, for instance models with fluid port connectors can be imported and the ‘Medium’ type is correctly set in the CyPhyML Component.

If the model or library does not conform to the Modelica Specification and/or the OMC API cannot load the package, then the automated import functionality is not available in the OpenMETA tools, requiring users to build the CyPhyML Components manually.

We are currently working on supporting a more complete set of the Modelica language and multi-fidelity models where one CyPhyML Component can be linked to more than one Modelica model and where the different Modelica models represent different level of modeling abstraction of the behavior of the physical component.

The OpenMETA tools already have a limited support for multi-fidelity component models, but they have to be built manually. For any CyPhyML Test Bench the component fidelity selection can be specified for a class of components, e.g., spring or damper component models.

## 2.3 Generating Modelica Models

Once a set of Modelica components are imported into the CyPhyML we can build design models, design space models and test-bench models. These models are composed through interfaces (i.e., connectors and parameters), which is sufficient information to generate composed Modelica models of test bench models for a design or for the entire design space.

The generated Modelica models preserve the hierarchical decomposition of the system and organize all generated models into packages and sub-packages based on the CyPhyML project structure to ease navigation in the generated model. Each generated component model, used in the design, ‘extend’ the referenced Modelica model and overwrites the parameters with the CyPhyML Component instance values.

From each dynamics CyPhyML Test Bench there are two generated models in the Modelica package that are used to run analysis. One of them is a simulation model and the other one is an augmented version of the simulation model for formal verification purposes.

Figure 2. Mass-Spring-Damper in Modelica

Figure 3. Mass-Spring-Damper design space in OpenMETA tools

Figure 4. Mass-Spring-Damper design space tree and alternative options

We use a Mass-Spring-Damper (MSD) system, which contains Modelica Standard Library components, as a simple use case to show the workflow and the results of the formal verification tool for two configurations from a CyPhyML Design Space. Modelica model of the MSD system structure is shown in Figure 2. Figure 3 depicts the design space in the OpenMETA tools, where each component *Mass*, *Spring*, and *Damper* contains alternative components. The hierarchical structure and alternative options are shown in Figure 4. There are

10 alternatives in each design container, thus the design space generates  $10 \times 10 \times 10$  (1000) configurations. We have selected two configurations (#1 and #8) for further analysis by the verification tool.

Configuration #1 and configuration #8 have the same architecture, i.e., the same number and kind of components and the same connections among the components, but configuration #1 uses Mass 9 ( $m=9$  kg), Spring 9 ( $c=9$  N/m), Damper 9 ( $d=9$  N.s/m) and configuration #8 uses Mass 3 ( $m=3$  kg), Spring 8 ( $c=8$  N/m), Damper 8 ( $d=8$  N.s/m).

Figure 5 shows configuration #1 of a generated Modelica model for formal verification. The verification model inherits the simulation model and includes: the definition of the requirement status (success, unknown, violated), all physical limit definitions (e.g. Limit1: maximum absolute force cannot exceed a certain value) and requirements for the system, and defines all conditions under which the limits (e.g.  $\text{abs}(\text{Spring.f}) > 17$ ) and requirements are violated.

```
model verif_MassSpringDamperAuto2cfigs_cfig1
  extends CyPhy.TestBench.MassSpringDamperAuto2cfigs_cfig1;

  // Requirement Definition
  type Requirement = enumeration(
    success,
    unknown,
    violated);

  // Limit-Checks definitions
  Requirement Limit1(start = Requirement.unknown, fixed=true)
  " Max absolute value limit-check on
  MassSpringDamper.Spring_1__Spring_9.flange_a.f";

  // Requirements-Checks

equation
  // Limit-Checks equations
  if Limit1 == Requirement.violated or
    MassSpringDamper.Spring_1__Spring_9.flange_a.f > 17 or
    MassSpringDamper.Spring_1__Spring_9.flange_a.f < -17 then
    Limit1 = Requirement.violated;
  else
    Limit1 = Requirement.unknown;
  end if;

  // Requirement-Metrics Checks equations

end verif_MassSpringDamperAuto2cfigs_cfig1;
```

Figure 5. Modelica model of MSD configuration #1.

## 2.4 Model translators and Job Manager

CyPhyML analysis model translators (i.e., analysis interpreters) are built to generate analysis packages from CyPhyML test benches, which contain domain tool specific input files, data structures, and scripts to perform the execution and collect results.

The OpenMETA tools can generate analysis packages for all test benches over the entire design space. This raises another scalability issue: executing all analysis packages may take significant time. In order to reduce the overall runtime, the META Job Manager [8] can run the individual/independent analysis packages in parallel either locally utilizing multiple CPU cores, or

on a remote compute cloud provided by the VehicleFORGE [8] platform. After analyses are executed, the results are stored locally.

## 2.5 Analysis Results

The raw analysis results are cumbersome and can be extremely difficult to compare. To address this issue, CyPhyML defines metrics for the key performance parameters of design configurations. These numbers, which are often driven by system requirements, provide the basis for design trade-offs and ranking, as well as for making decisions under specific circumstances about which design configuration is best.

Metrics are stored in a manifest file that contains the key information about the design configuration, test bench, and the projection of results. This single file is much smaller than the raw data and makes design space comparisons significantly easier. In general, we noticed roughly a three orders of magnitude size reduction when using only the compact manifest file (e.g. 15 GB of raw analysis data  $\rightarrow$  10 MB).

The OpenMETA tools provide a data visualizer called the Project Analyzer. The Project Analyzer can be used locally in a web browser or deployed on VehicleFORGE (or another server). It loads all analysis data from the manifest files (no data from raw files is loaded) and provides different visualization techniques to display results, visualize requirements, rank designs based on the user's weighting preference on metrics, show physical limit violations on components, display constraint plots, show formal verification results, etc.

**Figure 6.** Mass-Spring-Damper simulation results configuration #1 force on the spring component

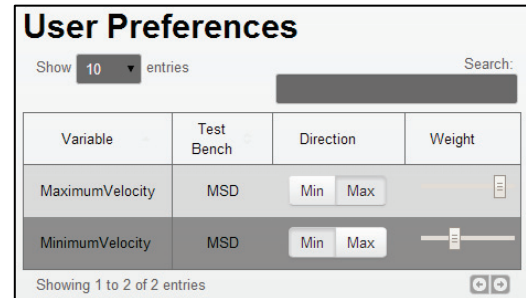

OpenModelica can be used to visualize the raw simulation results if needed. Figure 6 shows the force [N] on the spring component for design configuration #1.

The Project Analyzer provides various visualization techniques using different widgets to visualize the results over a design space. Figure 7 shows the parallel axes plot widget, where the vertical axes correspond to the metrics (velocities) and each colored line between the axes represent a design configuration. The require-

ments objective and threshold values are shown on the right hand side of the axes.

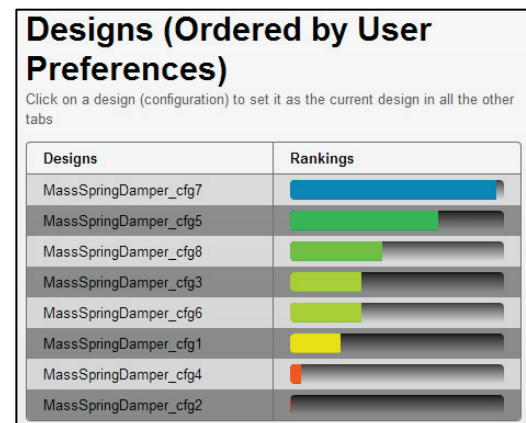

**Figure 7.** Project Analyzer parallel axes plot

**Figure 8.** Project Analyzer user preferences settings

**Figure 9.** Project Analyzer designs by user preferences and color coded based on requirements

**Figure 10.** Project Analyzer designs by user preferences and color coded based on ranking

Users can set their weighting preference (Figure 8) for each metric value, which would determine the ranking

of the designs shown in Figure 9 and Figure 10. Designs on each widget can be color coded based on requirements (Figure 9), ranking (Figure 10), limit violations, or design scores.

## 2.6 Simulation and Verification of Generated Modelica Models

We have chosen to separate the verification and the simulation models in the generated code. We aim to run the simulations as fast as it possible, since running the test benches over a design space can take significant time even if parallel execution is used.

Using the OpenMETA tools and the parallel execution capability provided by the Job Manager we run hundreds of design configurations over tens of test benches. The simulation model does not need to contain verification properties and unnecessary auxiliary variables. Therefore, the simulation can first be executed, and then a post processing script can validate the limit violations and requirements on the simulation results.

This approach will give us a faster execution time for simulation models. The OpenMETA tools use OpenModelica to execute the generated simulation models.

Modelica models for verification are translated to Differential Algebraic Equations using the OpenModelica Compiler. The Mass-Spring-Damper configurations are translated to DAEs and then a formal verification tool analyzes both configurations.

**Figure 12.** Verification results for MSD configuration #8.

The limit restrictions and requirements are the same for configuration #1 and #8. Figure 11 and Figure 12 depict the results of the formal verification results for configuration #1 and configuration #8 respectively. Section 3 and Section 4 describes the integrated formal verification method and reliability analysis in more detail respectively.

## 3 Qualitative Reasoning Module

The Meta tool suite includes a Qualitative Reasoning Module (QRM) which performs qualitative analyses of system behavior. In contrast to Modelica solvers which produce exact numerical results given exact numerical inputs and parameter values, qualitative simulators predict the possible time evolution of a system in qualitative terms.

Qualitative values are characterized by ranges, for example  $Q^+$  represents any possible positive value. Qualitative values can be demarcated with landmarks, for example  $[1, u]$  where the value lies between 1 and  $u$ . A qualitative analysis may show that a particular design cannot ever meet its requirements—something that is impossible to show with numerical solvers.

One challenge to more widespread use of Qualitative Reasoning is the lack of extensive qualitative model libraries. One cannot expect a designer to write their own qualitative models. Therefore we have spent considerable time and effort into automatically translating Modelica models into terms suitable for qualitative analysis.

Our translator starts with the exported DAE from OpenModelica. This has required significant extensions of model importers to qualitative algorithms. In addition, the DAE exporters have had to be extended to provide additional information. Qualitative reasoning requires declarative models. Any Modelica model used by AVM which is not purely declarative is being converted to declarative form manually.

Qualitative reasoning is most useful in early stages of conceptual design where the parameters, topologies, and requirements have not been completely articulated. Topologies which cannot possibly achieve customer requirements can be eliminated without having to determine specific parameters.

Qualitative analysis can also analyze a design which fails to meet some requirement and suggest qualitative parameter changes which will bring the design closer to meeting a requirement. The screenshot (Figure 13) illustrates analyzing a mass-spring-damper system to identify qualitative changes to meet a requirement.

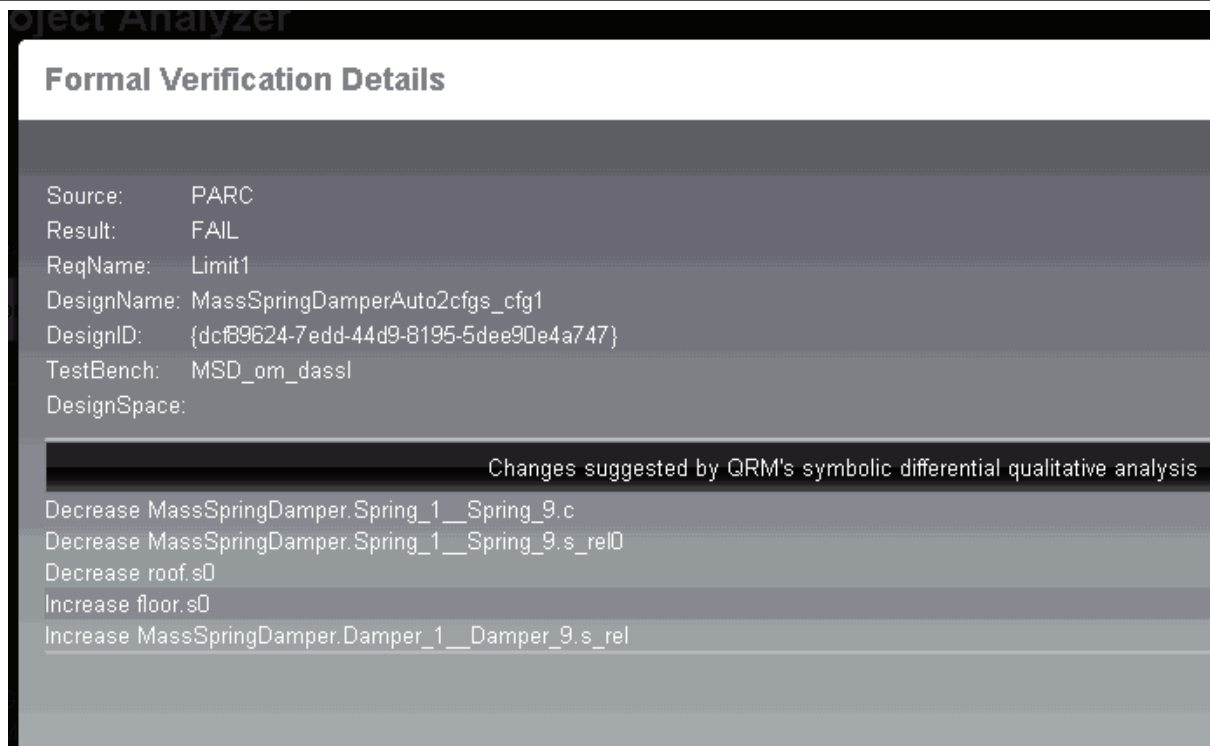

Figure 13. Using QRM for analysis of a mass-spring-damper system.

## 4 Reliability Analysis

The Meta tool suite includes a reliability analysis tool. This tool automatically allows a designer to evaluate the reliability of various components as well as various design configurations. The reliability tool has three major modules: (1) automatic construction of Modelica fault models, (2) determination of the fault probability distributions, (3) computing system reliability given (1) and (2).

Our fault augments takes a MSL model as input and automatically constructs its fault modes, which includes power port failures such as open and shorts as well as important parameter shifts. For each fault model, we construct damage maps which provide a probability density function for important parameters and is indexed by the type of material the particular component is constructed out of (e.g., steel), CAD properties, and Modelica variable values. The damage maps are constructed through a separate probabilistic process. More details can be found in [13]. In this paper we will focus on how the reliability tool is used by a designer (i.e., the third module).

Figure 14. Braking distance / the coefficient of friction

Suppose a designer needs to choose brake in their design (vehicle drive train) that will meet its stopping requirement of 28 m from 60 kph. Given a fault augmented model, we can determine stopping distance by running multiple Modelica simulations.

From the Modelica simulations we can see that the stopping criterion fails after a fault amount of 0.27. Using the reliability formula and given a reduction in friction the actual physical damage is 0.85.

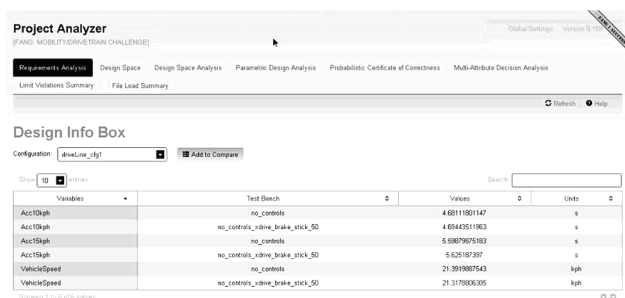

**Figure 15.** ACEI Wear damage / coeff. of friction.

Finally we refer to the damage map to determine the probability that the vehicle will meet its braking requirement after 75 missions.

**Figure 16.** ACEI Wear damage / cumulative distribution.

With the reliability tool the designer can choose the component, requirement, number missions, desired probability of success, etc.

**Figure 17.** Reliability tool.

The needed Modelica simulations required to render these reliability calculations are expensive. Our approach is to pre-compute as much as possible. For example, the damage maps are all pre-computed. For the simple vehicle model analysis presented here we have

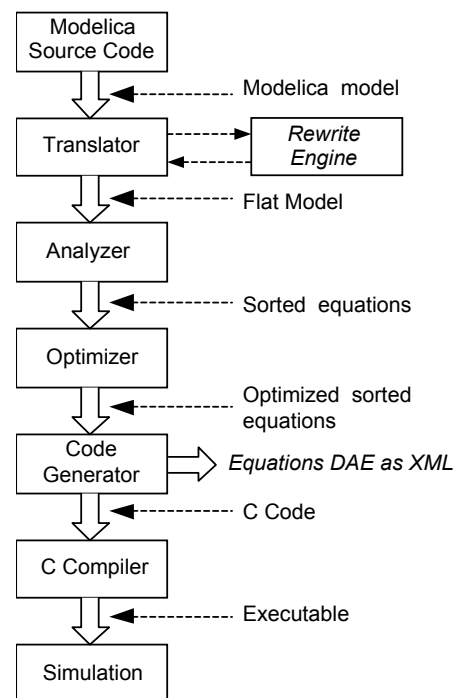

pre-computed all Modelica simulations (and use interpolation) to enable the reliability tool to respond instantly. However, for complex novel designs the reliability calculations will take hours and possibly days on a single machine. Fortunately, reliability calculations scale linearly with the number of processors.

## 5 OpenModelica Tool Support

OpenModelica is used in four different places in the OpenMETA tool chain:

- importing Modelica models and associating them with CyPhyML component models,
- performing simulations of composed Modelica models, i.e., CyPhyML test benches,
- analyzing Modelica models and automatically adding fault modes, and
- extracting Differential Algebraic Equations (DAEs) for formal verification tools.

The OpenModelica compiler (Figure 18) has been slightly extended to facilitate integration with the META Tool chain.

**Figure 18.** The OpenModelica compiler (OMC) structure and simulation execution. A rewrite engine and enhanced DAE XML output have been added for Meta Tool usage.

### 5.1 User-defined Rewrite Rules for Model Simplification

In order to make it feasible to apply formal verification to models they need to be simplified as much as possible so that their complexity is drastically reduced.

To support model simplification a *rewrite engine* for user-defined rewrite rules has been added to the OpenModelica compiler (Figure 18).

Note that this simplification could be applied by the formal verifier tool on the final DAE, but if the rewrite rules are applied as early as possible inside the Modelica compiler further simplifications can be discovered and applied.

The final model representation form as reduced and optimized symbolic equations is output in an XML representation for further processing by the Meta Tools QRM module.

The user defined rewrite rules have the form:

```
rewrite(old_expression, new_expression);
```

Note that `old_expression` and `new_expression` can contain special component references in the form of quoted identifiers starting with \$, for example: '\$1', '\$2', '\$x', '\$y', etc.

The part of the expression tree where the special component reference appear is bound to that component reference.

As an example, consider the rule:

```
rewrite(
  abs('$1'),
  if ('$1' >= 0) then '$1' else -'$1');
```

which could be applied to an expression:

```
abs(y + z)
```

In this case \$1 will be bound to `y+z` and the transformed expression becomes:

```
if ((x+y) > 0) then (x+y) else -(x+y)
```

The bounding operation is similar to pattern matching or unification in languages that support such features. Some examples of user-defined rewrite rules:

```
rewrite(
  abs('$1'),
  if ('$1' >= 0) then '$1' else -'$1');

rewrite('$1' ^ 2, '$1' * '$1');

rewrite(semiLinear(0.0, '$1', '$2'), 0.0);

rewrite(noEvent('$1'), '$1');

rewrite(
  Modelica.Fluid.Utilities.regStep(
    '$1', '$2', '$3', '$4'),
  if ('$1' > '$4') then '$2' else '$3');
```

The rules are loaded from a file given by the user and the rules are matched/applied to the expressions appearing in the abstract syntax tree.

Note that the application of the rules happen during semantic checking of expressions so that the resulting type before and after the application of the rule can be

checked. In the cases where the bound expressions are arrays the operation is applied for each element, for example:

```
rewrite(
  Modelica.Math.Matrices.isEqual('$1',
    '$2', '$3'),
  '$1'=='$2');
```

applied to:

```
Modelica.Math.Matrices.isEqual({{x,y},
  {z,w}}, {{a,b},{c,d}}, eps)
```

will result in:

```
x == a and y == b and z == c and w == d
```

One can see that in some cases not all variables are used as for example `eps` above. For the purpose of formal verification the given expression is enough as the `eps` is used only for robustness of simulation.

## 6 Integrated OpenModelica Meta Tools Environment

The following summarizes the main capabilities of the integrated OpenModelica – META Tools environment:

- Parse Modelica models (OpenModelica compiler API called through Python) and import model interfaces (parameters and connectors) into the META tool chain.
- Run simulations of composed Modelica models using the OpenModelica (OMC compiler).
- Be able to formally *evaluate verification properties* of system designs using OpenModelica and verification tools QR/HybridSal (XML DAE).
- OpenMETA tools can *compose simulation models over a design space* including different architecture variations in an automated way.
- Verification problems and simulation models can be encoded as *test bench*, which can be evaluated over a *design space*.
- Using the OpenMETA tools the *JobManager* provides sufficient capabilities to utilize all CPU cores in the user's computer.
- The analysis simulation/verification can run locally or on a remote execution cluster.
- Simulation and verification results are collected and visualized through a common interface called *Project Analyzer*.

## 7 Related Work

Automated verification of dynamic behavior of design models against formalized requirements is described in

[10] and [11]. A prototype of an integrated tool chain for model based functional safety analysis is presented in [12].

## 8 Conclusions

This paper has presented an overview of the META tools for design space exploration and design verification, and their integration with OpenModelica.

The integrated environment currently has four main uses of OpenModelica: importing Modelica models into the META tool model structure, performing simulations within test benches, analyzing Modelica models and automatically adding fault modes and extracting equations (DAEs) for formal verification tools, e.g. the QRM using qualitative reasoning.

A prototype of the integrated tool framework is in operation, being able to generate and simulate thousands of designs in an automated manner.

## Abstract

Modelica gives the possibility to compose more and more detailed models since model components can be reused. This means that simulation needs to be faster. One possibility is then to use multi-core technology. Recent advances with more than 1000 cores show the potential.

The problem is then how to utilize this enormous processing power in a user friendly way. Partitioning needs to be made automatically. Modelica gives good possibility to automatically partition the model equation execution into separate threads since it is a declarative language based on equations.

This paper describes a method to automatically parallelize model equations implemented in Dymola. A speed-up of 3.4 times has been achieved using 4 cores/8 threads.

*Keywords: Modelica; Multi-core; Automatic partitioning*

## 1 Introduction

Modelica gives the possibility to compose more and more detailed models since model components can be reused. This means that simulation needs to be faster. One possibility is then to use multi-core technology. Recent advances with more than 1000 cores show the potential. One example is the Kalray MPPA (Multi-Purpose Processor Array) Technology (<http://www.kalray.eu/>). The MPPA 256 has 256 cores on one chip.

The problem is then how to utilize this enormous processing power in a user friendly way. Partitioning needs to be made automatically. Modelica gives good possibility to automatically partition the model equation execution into separate threads since it is a declarative language based on equations. (Aronsson, 2002, 2006) discussed automatic partitioning algorithms but speed-up was only achieved in special cases.

This paper describes technology to automatically parallelize model equations. Results using the implementation made in Dymola are included. Thermodynamic and electrical examples are discussed in detail. A speed-up of 3.4 times has been achieved using a laptop with Intel(R) Core i7-3740QM CPU @ 2.70GHz with 4 cores/8 threads.

## 2 Algorithms for Parallelization

The goal is to make a static scheduling of the equation execution. To find the optimal schedule is very complex, so various heuristics needs to be utilized. The first phase is to investigate which equations that could be executed in parallel. In this phase, the number of possible threads is not utilized.

In order to balance the efforts of executing the parallel sections, we need to have some estimates of the cost of executing different parts. Thus, the equations are analyzed and manipulated in the ordinary way until we have a sequence of calculating derivatives and variables at a given point of time. The calculations may include simple assignments, calls to Modelica functions or external functions and solving linear, nonlinear, mixed discrete/real systems of equations. An element in this sequence will be called a block node and it includes a set of solved equations and a set of variables that are solved by the node. The ordering of the block nodes is typically obtained by making a Block Lower Triangular (BLT) partition of the problem. The BLT partitioning defines a partial ordering meaning that a node can be executed if all block nodes with lower numbers have been executed. There may be other orderings that also may be feasible. If two successive blocks do not need each other's result, the order can be exchanged. They can in fact be executed in parallel. The major steps to investigate what can be executed in parallel are:

1. Build a dependency graph including all block nodes. Let the edges represent the dependencies between the nodes such that if node  $N_i$  needs the input of a variable  $v$  be-

- longing to node  $N_j$  there is an edge between  $N_i$  and  $N_j$ . We can make the edges directed:
- For  $N_i$  it is a “need” edge meaning that it needs the results of  $N_j$ . The BLT partitioning has sorted  $N_j$  before  $N_i$ .
  - For  $N_j$  it can be viewed as “used by” edge.
- Parallelization: Search for all **source** blocks in the BLT graph, i.e. blocks which does not depend on other blocks (no outgoing needs edges) and collect them in layer  $L_i$ , which corresponds to equations or systems of equations that can be solved independently of each other.
  - Delete all nodes in  $L_i$  from the block node graph and delete all edges to them.
  - If there are still nodes in the graph, increase  $i$  by one and go to step 2.
  - The sets  $L$  define a parallelization and the calculations are given starting from  $i=1$ .

We developed this algorithm in October 2009 and made a test implementation. However, our run-time infrastructure was not completely reentrant, so we were not able to make any simulation tests. Casella proposed in 2013 (Casella, 2013) a very similar algorithm but did not present any run-time speed-up results. However, in step 2, this algorithm searched for **sinks**, i.e. it was a dual algorithm.

Unfortunately, using the result of these basic algorithms for parallelization doesn’t give desired speed-up. The reason is that the obtained sections of a layer  $L_i$  are normally too small so overhead will give longer execution times. It is necessary to aggregate blocks into a section so the execution of a section outweighs the effort to set up and start the thread execution.

The approach to search for sources can be viewed as performing a calculation as soon it is possible. This approach can be taken bit further, if we consider the block nodes in the order defined by the BLT sorting and if we are collecting block nodes for  $L_i$  and a block node only has need edges from one section we add that block node to that section instead of deferring the calculation to  $L_{i+1}$ . The approach to search for sinks can on the other hand be viewed as performing the calculations just-in-time. We are then considering the nodes in the reverse order defined by the BLT sorting. If we are collecting block nodes for  $L_i$  and a block node only has a needed edges from one section we add that block node to that section instead of already doing the calculations in  $S_{i+1}$ . Please, recall that in this approach the sets are ordered in reverse calculation order.

In many cases the sets will include more parallel sections than we have cores. Thus, it is useful to merge sections within a set to make each section bigger to beat overhead. To get the sections balanced we need to have some estimate of the effort needed to perform the calculations of each block node. That is a difficult task for many reasons such as the solving of a non-linear problem may take different number of iterations. We have developed heuristic to get an estimate of the number of arithmetic operations needed to execute a block node. This includes also estimating the complexity of Modelica functions. Fortunately, we can make the result less sensitive to the estimates by generating code for more sections than we have cores. If we order the sections in estimated complexity order with the most complex first, the execution will start with them. If some estimates are bad or one nonlinear system needs more iteration, the other cores can be kept busy by handling remaining sections. Each section should have a minimum estimated effort.

From the two basic approaches discussed above indicates there may be a freedom in which parallel layer a calculation may be put in. To get fast translation it is not possible to check and evaluate all scheduling possibilities. To simplify the problem we focus on the most complex blocks and try to get as many of them in the same layers.

When the parallel sections of each layer have been identified, we need to be concerned with data. If data used and updated by different cores are adjacent, there is a risk of performance degradation due to *false sharing of cache lines*. Even if one core does not write the same double precision number as used by another core, the two variables might reside in the same cache line, typically 64 bytes of memory. We overcome this false sharing by adding padding, of typically 64 bytes, between the variables sets of the different sections.

### 3 Parallel Code for Equations

Consider the following model:

```
model ParallelCodeGeneration
  input Real u, U;
  Real x1, x2, x3;
  Real y1, y2, y3;
  Real X1, X2, X3;
  Real Y1, Y2, Y3;

  equation
    der(x1) = f1(x1, u);
    y1 = g1(x1, u);

    der(x2) = f2(x2, y1);
    y2 = g2(x2, y1);
```

```

    der(x3) = f3(x3, y2);
    y3 = g3(x3, y2);

    der(X1) = F1(X1, U);
    Y1 = G1(X1);

    der(X2) = F2(X2, Y1);
    Y2 = G2(X2);

    der(X3) = F3(X3, Y2);
    Y3 = G3(X3);
end ParallelCodeGeneration;

```

It consists of 3 dynamical systems with direct term (g1, g2, g3) coupled in series and 3 systems in series without direct term (G1, G2, G3).

The partitioning of the equations into layers of parallel sections as described above corresponds to a fork-join code generation scheme. OpenMP supports this scheme by using simple pragmas in the C-code. The following code will thus be generated by the proposed parallelization algorithm:

```

#pragma omp parallel
{
  #pragma omp sections
  {
    #pragma omp section
    {
      der(x1) := f1(x1, u);
    }
    #pragma omp section
    {
      y1 := g1(x1, u);
    }
    #pragma omp section
    {
      der(X1) := F1(X1, U);
    }
    #pragma omp section
    {
      Y1 := G1(X1);
    }
    #pragma omp section
    {
      Y2 := G2(X2);
    }
  }
}
#pragma omp parallel
{
  #pragma omp sections
  {
    #pragma omp section
    {
      der(x2) := f2(x2, y1);
    }
    #pragma omp section
    {
      y2 := g2(x2, y1);
    }
    #pragma omp section
    {
      der(X2) := F2(X2, Y1);
    }
    #pragma omp section
    {
      der(X3) := F3(X3, Y2);
    }
  }
}

```

```

}
// Sequence of calculations
der(x3) := f3(x3, y2);

// Result calculations
y3 := g3(x3, y2);
Y3 := G3(X3);

```

Two parallel layers will thus be used followed by a sequence (of one block). The last two equations are not needed for solving the differential equations only to enable plotting.

Note that *no* mutual exclusion locks are needed since updating a variable is done only in one block, i.e. in one section and reading is always done in later layers, i.e. after resynchronization.. Between layers of parallel code, usual sequential code is used typically when potential parallel sections would be too small and sequential execution is faster.

## 4 Example: Electrical Circuit

Consider a Spice3 model of a 4-bit ripple-carry adder. The model is available in the Modelica Standard Library:

Modelica.Electrical.Spice3.Examples.

Spice3BenchmarkFourBitBinaryAdder

The model adds two 4-bit numbers and is built out of four two-bit adders, Figure 1:

Figure 1: Four-bit adder

The two-bit adders are built out of two one-bit adders, Figure 2.

Figure 2: Two-bit adder

The one-bit adder is built out of nine NAND gates, Figure 3.

**Figure 3: One bit adder**

Each NAND gate has 5 BJT transistors and 3 diodes. The total model contains 180 BJT transistors and 108 diodes. There are 4640 unknown variables of which 324 are state variables. Many systems of equations appear:

Sizes of linear systems of equations: {5, 11, 5, 5, 5, 5, 5, 5, 66, 5, 11, 5, 5, 5, 5, 5, 66, 5, 11, 5, 5, 5, 5, 5, 66, 5, 11, 5, 5, 5, 5, 5, 62, 5, 16, 5, 16, 5, 16, 5, 16, 5, 16, 5, 16, 5, 16, 5, 16}

Sizes after manipulation of the linear systems: {0, 3, 0, 0, 0, 0, 0, 0, 26, 3, 0, 0, 0, 0, 0, 0, 26, 0, 3, 0, 0, 0, 0, 0, 26, 0, 3, 0, 0, 0, 0, 0, 24, 0, 7, 0, 7, 0, 7, 0, 7, 0, 7, 0, 7, 0, 7, 0, 7, 0, 7}

[illegible]

Sizes after manipulation of the nonlinear systems: {4, 4, 4, 4, 4, 4, 4, 4,  
4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4, 4}

Simulating this model for 1e-7 seconds takes 40.9 seconds on using a laptop with Intel(R) Core i7-3740QM CPU @ 2.70GHz with 4 cores/8 threads. This laptop has been used for all timings in this paper.

The BLT (Block Lower Triangular) structure is shown in Figure 4:

**Figure 4: BLT structure for 4 bit adder**

The BLT blocks are the small green squares along the diagonal. Note, that the BLT structure is not unique. The grey lower part has either zeros or ones. The rows and columns has been permuted according to the proposed partitioning algorithm (starting by searching *source* blocks) to show the triangles of zeros below the diagonal. These zeros are utilized when the layers of blocks to be executed in parallel are formed.

The layers can be compressed vertically as shown below to illustrate the parallel execution of blocks that don't need input from each other, Figure 5.

**Figure 5: Initial parallel schedule**

It can be noticed that many small systems of equations are presented for which the cost of evaluation is very small. The cost of evaluation is estimated by counting the number of operations needed. A fixed number of iterations is assumed for nonlinear systems of equations and for for-loops and while-loops within functions. The corresponding diagram when the vertical size has been replaced by estimated number of operations (divided by 50) is shown in Figure 6.

**Figure 6: Parallel schedule (cost horizontally)**

Blocks on the critical path are marked red. The estimated total number of operations are (sequentialPathLength) 424 198. The criticalPathLength = 28 967. The AmdahlSpeedUpFactor = sequentialPathLength / criticalPathLength = 14.7.

The pathLength for this particular schedule using numberOfLayers=15 and numberOfCores=126 is 80 225. The estimated speedUpFactor = 5.3.

The corresponding schedule produced by the dual algorithm (first searching for sinks) is shown in Figure 7.

**Figure 7: Parallel schedule using dual algorithm**

The characteristics of this schedule are: pathLength = 60 697, speedUpFactor = 7.0, numberOfLayers = 15, numberOfCores = 325.

These schedules are not realistic for the target architectures with fewer cores available today. The granularity is too small since some of the sections just have a few operations. So merging of blocks must be done. Furthermore, it can be noted that some large blocks have ended up in different layers. In many cases, there is a freedom to move blocks between layers still not violating the data dependency. By appropriate heuristic rules, it is possible to achieve the schedule in Figure 8. In this case the maximum number of sections has been constrained to 4.

**Figure 8: Parallel schedule with max 4 sections**

The following characteristics is achieved: pathLength = 114 998, speedUpFactor = 3.7, numberOfLayers = 6, numberOfCores = 4.

The schedules presented are essentially Gantt charts with time advancing downwards. By using fixed width of the rectangles instead of width proportional to the number of unknown variables, we get Figure 9.

**Figure 9: Gantt chart for 4 section schedule**

The simulation time using this schedule is 16.5 seconds, i.e. a speedup of  $40.9/16.5 = 2.48$ . For the dual algorithm (first searching for sources), the simulation time becomes 18.0 seconds.

The utilization of the cores is quite low as can be seen in Figure 10:

**Figure 10: CPU usage with max 4 sections**

It makes sense to increase the maximum number of sections to 8, 16 or even 32. The best simulation times achieved was 13.9 seconds, i.e. a **speed-up of 2.94**. The utilization of the cores then becomes 80%, Figure 11.

**Figure 11: CPU usage with max 16 sections**

The actual execution times are logged during simulation using high resolution timers and are presented as follows:

Name of block	Total CPU[s]	Min[us]
Seq 2 (71)	0.009	0.22
Par 3 [2] (59)	1.571	32.85
Seq 4 (45)	0.010	0.14
Par 5 [16] (98)	6.201	105.86
Par 6 [4] (428)	2.458	86.21
Par 7 [4] (49)	1.623	32.76
Par 8 [2] (36)	0.508	10.73
Seq 9 (20)	0.010	0.26
Par 10 [16] (87)	0.988	28.51

Seq  $i(m)$  means sequential layer  $i$  with  $m$  BLT blocks, i.e. no parallelization. Par  $i[n](m)$  means parallel layer  $i$  with  $n$  parallel sections and  $m$  BLT blocks. It is then seen that layer 5 has larger execution time than layer 6 contrary to the estimated times shown in the Gantt diagram. The reason is that layer 5 has 16 sections but only 4 cores are available, i.e. some of the sections must be executed sequentially.

## 5 Example: Evaporator

Consider simulation of a model of an evaporator included in the AirConditioning library as `AirConditioning.Examples.Evaporator` model and shown in Figure 12.

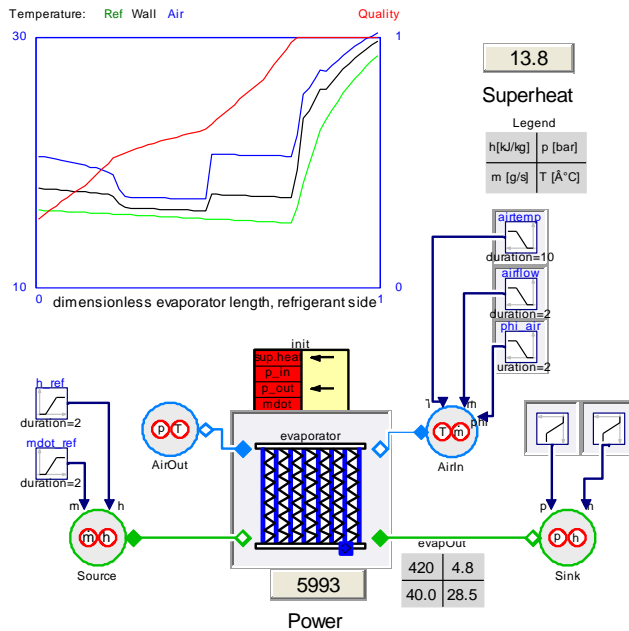

Figure 11: Evaporator model

The geometry of the evaporator for both air and refrigerant are discretized into segments. The example given in `AirConditioning` has `evaporator.n_segAir = 1` and `evaporator.n_segRef = 3`, which gives that the refrigerant is discretized into 18 cells along the flow direction. Each of these cells as well the sink has pressure and enthalpy as continuous states and there is additionally 18 continuous time states for the wall temperature giving a total of 56 states. The major computational task is to calculate the thermodynamic properties from the state variables. There are 9 non-linear systems of size 23 and 9 non-linear systems of size 21. The difference is due to the geometry of the heat exchanger. The tearing procedure results in problems with 3 iterations variables for all of them. If we set the stop time to 100 s, it takes 2.44 s to

simulate it on a normal laptop. We are here mainly interested in the speed-up when parallelize the calculation, so the absolute time is of less interest, however, it is of interest to consider the absolute time and number of calculations, because when the calculation are sufficiently short, the overhead to start and synchronize the parallel calculation the overhead will make the parallelized calculations take longer time than running then in sequence on one processor.

A causality analysis gives that we can first solve 9 of the systems in parallel followed by some other calculations and thirdly the remaining 9 systems.

Partitioning of the code with maximum of 16 sections can be represented in the graph in Figure 12. Green rectangles represent BLT blocks. These are merged into sections which are outlined in blue. The critical path is marked in red.

Figure 12: Schedule for Evaporator using max 16 cores

It takes about 45  $\mu$ s to solve such a nonlinear system of equations. **With 4 cores/8 threads we get a speed-up factor of 2.1.**

Let us make the model more complex by making a finer and more desirable discretization by setting `evaporator.n_segAir = 5` and `evaporator.n_segRef = 10`, which gives that the refrigerant is discretized into 60 cells along the flow direction. Each of these cells as well the sink has pressure and enthalpy as continuous states and there is another 60 continuous time states for the wall temperature giving a total of 182 states. There are now 30 systems of size 112 and 30 systems of size 110. The tearing procedure results in problems with 11 iterations variables for all of them. The simulation time becomes now 58.8 s, compared to 3.7 s for when using a less fine discretization. A causality analysis gives that we can first solve 30 of the system in parallel followed by some other calculations and thirdly the remaining 30 systems can be solved in parallel. It takes 60-90  $\mu$ s to solve such a system. We can parallelize these computations. **With**

**4 cores/8 threads the factor is 3.4.** The calculations between the systems of equations can be split into two parts that can be run in parallel. One part takes  $2.2\ \mu\text{s}$  to execute and the other takes  $6.7\ \mu\text{s}$ , so running them in series takes  $8.9\ \mu\text{s}$ . If we run them in parallel it takes  $23\ \mu\text{s}$ , due to the overhead to start up and synchronize parallel threads.

## 6 Example: Multi-Body Systems

Let us consider simulation of multi-body systems. A major task is to invert the mass-matrix to solve for the accelerations. If the system has kinematic loops there are additional non-linear and linear systems. The factorization of a Jacobian is a major task when solving a system of equations. However, when parallelizing that, it gave faster calculations only if the size of the Jacobian was greater than  $300 \times 300$ .

Another major task is calculation of forces and accelerations. For a tree structured mechanism, there are obvious possibilities to parallelize each branch of the tree into different threads. Such possibilities will be investigated in the future.

### 6.1 Real-Time Simulation and Inline Integration

What has been discussed above applies to hardware-in-the-loop simulation (HILS) as well as when variable step-size integration methods are used.

For HILS of stiff models such as multibody systems including bushings, implicit methods are needed. Inline integration (Elmqvist, et.al., 2002) can then be used. It means that the discretization formulas are merged with the model equations and the entire merged set of equations is symbolically transformed.

The parallelization method can be used on the merged set of equations. However, implicit methods typically give one large system of non-linear equations to solve, i.e. the above method is not useful as described.

To handle this situation, we have introduced a **decouple operator** which delays the signals one step corresponding to changing from an implicit relationship to an explicit. The result is that the large system of equations decomposes into smaller systems that both are faster to solve and that can be solved in parallel.

Using this technique, we have been successfully simulated vehicles with about 150 DOFs (Degrees-of-Freedom) in real-time using a 1 ms step size and implicit Euler. By decoupling the front and rear wheel suspensions respectively from the chassis

(having large mass) and by decoupling each wheel from the wheel suspensions we achieved a speed-up of 1.5. The two decoupling elements decoupling front and rear suspensions from the chassis can be seen in the VDL (Vehicle Dynamics Library) diagram in Figure 13:

Figure 13: Decoupling of VDL model

Parallelizing the resulting smaller non-linear systems of equations gave a **further speed-up of 2.8** with 4 cores/8 threads.

## 7 Conclusions

Modelica is well suited for automatic parallelization of equation execution using many cores. We have described a technique for such automatic partitioning. The obtained results are good for models from various domains. For a thermo-dynamic model a speed-up of 3.4 was achieved, for electrical 2.9 and for mechanical HILS 2.8 using 4 cores/8 threads.

# A toolchain for Rapid Control Prototyping using Rexroth controllers and open source software

Nils Menager   Niklas Worschech   Lars Mikelsons  
Bosch Rexroth AG  
Rexrothstr. 3, 97816 Lohr a. Main

## Abstract

Taking a look at project costs from a financial point of view, the commissioning times of new industrial systems become more and more important, as they significantly drive the costs. Hence, the reduction of commissioning times is part of current research. Besides the use of simulation and the coupling between hardware and software (Hardware-In-The-Loop-Simulations), *Rapid Control Prototyping* offers a huge potential to reduce commissioning times. Until now, most of the toolchains use special hardware in combination with commercial simulation software, which leads to some serious drawbacks. In this work, a toolchain for Rapid Control Prototyping using industrial controllers and open source software is presented.

## 1 Introduction

### 1.1 Motivation

According to the V-model of mechatronic product development (VDI 2206, [1]), the first step during the design of a new industrial system, after a rough precalculation of the required components, is to set up a simulation model of the system under consideration. Therefore, at Bosch Rexroth, our in-house tool *Rexroth Simster* is used. *Rexroth Simster* is a simulation environment, which allows object-oriented modelling of technical, mainly mechanical, electrical and hydraulic systems. Clearly, the tool includes powerful numerical solver to perform the simulation. After suitable components and parameters are determined inside the simulation environment, the controller concept has to be tested using a real hardware controller. At this point, until now, the simulation model of the controller

is not used any further and the controller is set up from scratch inside the development environment of the controller. At Rexroth, mostly *IndraWorks* as standard tool for the development of controller algorithms and the design of the whole controller is used. In many cases, even the developed controller structure inside the simulation tool is not used anymore. Instead, predefined standard control algorithms are used.

However, it is clearly desirable to adapt the complete control algorithm from the simulation environment. There are already possibilities to use virtually designed control algorithms on real-time operating systems using Hardware-In-The-Loop-Setups. Two possibilities are using a dSPACE [2] system or a xPC system in combination with *Matlab/Simulink* [3]. Though, using such a toolchain leads to three serious drawbacks. First, these systems are very expensive. Second, even in that case the control algorithm has to be re-implemented on the real control hardware after testing on the real-time system. Furthermore, it has to be taken into account that the usage of such commercial real-time systems leads to dependencies to external software (e.g. *Matlab/Simulink*). Clearly, such a dependency for the generation of code for the PLC (*Programmable Logic Controller*) is not desirable. Moreover, if new features should be implemented, this is a big disadvantage, because the code generation of the commercial tools can not be modified.

The aim of this work is to set up a toolchain for Rapid Control Prototyping with a Rexroth controller (IndraControl L45) using open source software and Modelica for the modeling part, i.e. a toolchain, which is completely independent from external software and hardware. To be more precise, this toolchain enables the engineer to transfer virtual controller models modeled in Modelica to standard Rexroth controllers. To validate the functionality, in this contribution, the controller is used in a Hardware-In-The-Loop setup. The

validation of the controller in combination with a real system is part of current work.

## 1.2 Outline of this paper

In the first section of this paper, a short introduction into Rapid Control Prototyping is given. Furthermore, a standard toolchain for using Rapid Control Prototyping nowadays is discussed. In the second section, after requirements for the toolchain have been defined, the specific parts of the toolchain are presented. The functionality of the toolchain is finally verified using a Hardware-In-The-Loop setup consisting of a real Rexroth hardware controller running controller code of an industrial control algorithm created in Modelica and a model of a hydro-mechanic system. In the last part, a short summary and an outlook on further investigation is presented.

## 2 Rapid Control Prototyping

Rapid Control Prototyping is a computer-aided method for developing and testing control algorithms quickly on real-time operating systems. This approach allows to investigate how the control algorithm will behave later on the real hardware controller. Rapid Control Prototyping includes all steps between the definition of the controller specifications and the implementation of the final control algorithm. The single steps during the Rapid Control Prototyping process are shown in the V-model in figure 1. The left part of the V-model shows the way from the specification of the requirements to the implementation of the controller,

Figure 1: V-model showing the Rapid Control Prototyping process

in the right part the functionality of the implemented algorithm is verified. The functionality of the algorithm is then compared to the requirements specified at the beginning of the cycle. If there are differences between the required specifications and the actual functionality, another iteration cycle is necessary. This procedure is repeated until the actual behavior of the controller and the specifications fit together.

### 2.1 dSPACE/Matlab

Nowadays, the usage of Rapid Control Prototyping is already standard in different industry branches, e.g. the automotive industry. Therefore, for example dSPACE (*Digital Signal Processing And Control Engineering*) systems can be used. On a dSPACE box a real-time operating system is working which allows to execute code in real-time on the device. To generate the code, e.g. special toolboxes from *Matlab* can be used. These toolboxes allow to generate executable code for the dSPACE box in a very short time. Using this toolchain it is possible to develop and test control structures on a real-time operating system in an easy and fast way.

Although this method offers the possibility to test algorithms quickly, it does not avoid the re-implementation on the final hardware device, which is a big disadvantage. Besides the fact, that a re-implementation is time consuming and a possible error source, the portability is potentially incalculable. It cannot be guaranteed that the controller on the final target behaves in the same way as the controller on the test device. Other disadvantages are the costs of such a dSPACE system and the dependencies to the commercial software.

Because the *Matlab Code Generation* only works for special operating systems and special hardware, there are no direct possibilities to adapt the code generation for other devices like the Rexroth controller. Of course, it could be tried to wrap the code could for the use on other devices, but even in this case, this code has to be compiled for the target operating system. If only one single part of the code cannot be compiled for the operating system, it is impossible to execute the code on the hardware. Hence, it is necessary to develop a toolchain, which is open source and therefore applicable to different hardware devices. The development of such an open source toolchain is the topic of this work.

### 3 Realization of the toolchain

For the realization of the toolchain, clearly, different tools are needed. The structure of the toolchain is shown in figure 2. The starting point is the simulation environment *Rexroth Simster*. As already said in the introduction, the first step during the development of a new system is to set up a simulation model of the system and the controller inside the simulation environment. The simulation tool *Rexroth Simster* will, in one of the next releases, support both the usage of models from an internal library (written in C/C++) and of Modelica models. It makes sense to use Modelica models, because they offer three big advantages. The first one is, that Modelica models are easy to create and support an object-oriented modeling structure, either using a graphical user interface or the Modelica editor. Second, in order to simulate Modelica models, they have to be compiled to C/C++. There exist both commercial (e.g. *Dymola*) as well as open source (e.g. *OpenModelica*, *JModelica*) Modelica-compilers. In this work, of course the open source *OpenModelica*-compiler (OMC) is used. Furthermore, Modelica is a widespread language, which is used frequently in the industry.

The controller model shall then directly be used on the real PLC. The PLC used here is a common Rexroth controller (Rexroth IndraControl L45). Therefore it is necessary to compile the model of the controller for the operating system of the hardware. The real-time operating system running on the hardware is *VxWorks*. To execute the code and run the simulation on the PLC, a simulation core, which runs and manages the simulation, is additionally required. This simulation runtime has also to be compiled for the operating system *VxWorks*. To compile the system and the runtime and load the compiled libraries onto the hardware, the development environment *WindRiver Workbench* is used. This environment includes among other things a *VxWorks* compiler. The simulation of the controller model can then be executed in parallel to the main thread on the PLC. This first step, to compile and load the model on the PLC, is shown via the grey, dashed arrow in figure 2.

To allow the exchange of data between the PLC and the simulation environment during a HiL-simulation, an interface between the newly created thread running the controller code (controller thread) and the original *IndraWorks* thread (main thread) is required. To get access to the Rexroth IndraControl L45, the soft-

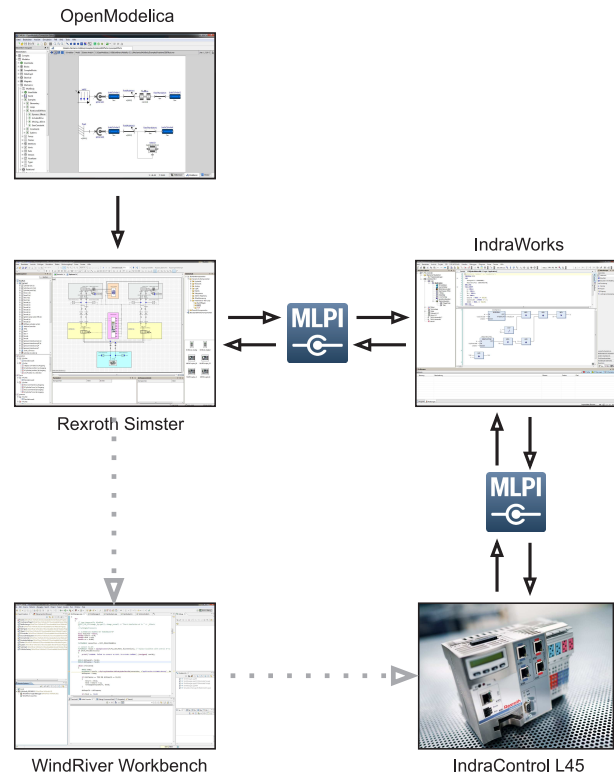

Figure 2: Structure of the toolchain

ware *IndraWorks* is used. *IndraWorks* is a standard tool for the development of control algorithms and the design of Rexroth PLCs. The connection between the controller thread and the main thread is realized with a function block according to IEC 61131 [4] inside the *IndraWorks*-application, which is used as an interface. In order to run the HiL-simulation, data has to be exchanged between the PLC and *Rexroth Simster*. Therefore, the MLPI (*Motion Logic Programming Interface*) is used [5]. The MLPI is a programming interface for high level programming languages (C/C++/C#/VBA/Java/LabVIEW/...). It can be used to write applications, which can be used to configure and run a Bosch Rexroth controller which supports the MLPI interface technology, like the IndraControl L45.

#### 3.1 Used software components

In the following sections, a short overview and more detailed information about the tools used in this work are given.

##### 3.1.1 Rexroth Simster

The simulation environment *Rexroth Simster* is an in-house tool developed by Bosch Rexroth. It covers multiple domains (mechanic, hydraulic, electric) and has

been developed for the design and optimization of controlled automation systems. The component library includes both generic and Rexroth specific components, which can simply be placed on the worksheet using drag and drop. *Rexroth Simster* includes a special simulation core. This simulation core offers an interface for models from the standard *Simster* libraries, which are implemented in C/C++. The C/C++ code generated by the *OpenModelica*-compiler implements the same interface. Thus, the simulation core can handle both models from the own internal library and Modelica models. Detailed information about the developed simulation runtime is given in [6].

### 3.1.2 WindRiver Workbench

*WindRiver Workbench* is an eclipse-based development environment for *VxWorks* and is used in version 3.3. *VxWorks* is a real-time operating system, which is mainly used in embedded systems and is the operating system running on Rexroth hardware controllers. Included in the development environment is a *VxWorks* compiler, which generates executable code from C/C++-code. The tool is used to compile both the controller model and the simulation core for the use on the hardware controller. The classes inside the simulation core are compiled into dynamically linked libraries, which leads to *.out*-files. These *.out*-files have then to be moved to the internal flash card of the Rexroth hardware. This is done using an FTP client.

### 3.1.3 IndraWorks

*IndraWorks* is a tool developed by Bosch Rexroth and is used as standard tool for the development of control algorithms and the entire configuration of the PLC. Inside *IndraWorks*, an application to run on the hardware can be created. After having configured the connection parameters (IP address, type of connection), the algorithms are developed using the IEC 61131-3 standard PLC programming languages. Furthermore, additional languages especially for the use of motion commands (PLCOpen) are available. During the runtime of the controller, the process can be visualized and monitored using plotter and other visualization tools.

### 3.1.4 Motion Logic Programming Interface

The *Motion Logic Programming Interface* is an interface supporting many high level programming interface and is also developed by Bosch Rexroth. Using

this interface, it is possible to write applications to configure and run Bosch Rexroth devices which support the MLPI interface technology. It contains a set of headers and libraries. There are 8 different libraries, which allow access to different parts of the controller:

- *mlpiAPILib* includes functions to connect and disconnect MLPI
- *mlpiSystemLib* includes functions to read system information like temperature, diagnosis data and the firmware version
- *mlpiParameterLib* includes functions to read/write parameter
- *mlpiLogicLib* includes functions to start/stop/reset the PLC, load PLC programs, browse/read/write symbol variables
- *mlpiMotionLib* allows access to general motion functions, single axis motion, cyclic commands and synchrone axis motion
- *mlpiContainerLib* allows cyclic read/write access with fast container buffer mechanism
- *mlpiWatchdogLib* includes functions to monitor the user application
- *mlpiTraceLib* includes functions for the trace configuration and to add, collect and view debug information.

There are four different MLPI toolboxes, each supporting a different programming language. Here, the toolbox for C/C++ is used. In this work, MLPI is used on the hand side to realize the data exchange between the simulation tool *Rexroth Simster* and the hardware controller. Furthermore, MLPI is used as interface between the user and the controller to change controller parameter inside the controller code. The structure and functional principle of MLPI is explained in [5].

## 3.2 Connecting the different components to the toolchain

To ensure the functionality of the toolchain, some additional aspects must be considered while connecting the different parts to the toolchain. The different aspects are discussed in the following, each in an own subsection.

### 3.2.1 Modifications inside the simulation core

An important point is the library handling in *VxWorks*. Hence, each location inside the code loading a library has to be modified. To ensure the functionality in both the new operating system (*VxWorks*) and the old environment (*Microsoft Windows*), pre-processor commands are used to decide which implementation is used. Using this method the same runtime can be used in both *Rexroth Simster* and on the PLC, which is an important requirement. To load dynamic libraries in *VxWorks*, the following basic framework has to be used:

```
int libraryFile = open("lib.out", O_RDONLY, 0777);
if (libraryFile == ERROR)
    // Error loading library

MODULE_ID c_moduleId = loadModule(libraryFile,
    LOAD_ALL_SYMBOLS);

close(libraryFile);
if (c_moduleId == NULL)
    // Unable to load as module

extern SYMTAB_ID sysSymTbl;
SYM_TYPE symType;
double (*funcPtr)(int);

if (symFindByName(sysSymTbl, "name",
    (char**) &funcPtr, &symType) == ERROR)
    // Symbol not found

double a = funcPtr(2);
```

After the library is loaded by the *open* command, all symbols are loaded using the *loadModule* function. This allows to get access to the functions inside the library. The next step is to create a function pointer. The function pointer in this example points on a function, which gets an integer as input variable and which returns a double value. The last step is to search a specific function in the symbol list using the *symFindByName* function. This function pointer can then be used to call the function inside the library.

### 3.2.2 Synchronization of the HiL-setup

The next aspect is the synchronization between the simulation of the system inside *Rexroth Simster* and the code execution on the PLC. It is clear, that both processes have to run synchronized, so that the exchanged data fit together. *Rexroth Simster* is a windows application and therefore, without any modifications, not real-time capable. That means, that the calculation time depends on the complexity of the model and the workload of the used operating system. Thus, the simulation can be faster or slower than real-time. In contrast, a PLC is a hard real-time system with a fixed cycle time. At the beginning of one cycle, the

Figure 3: UML Diagram showing the synchronization

inputs of the controller are read. Then, the control algorithm is executed and the output data based on the input data is computed. The last step is to write the calculated values to the output. Therefore, the controller expects input signals in real-time. Using a standard PLC containing a standard *IndraWorks* application (i.e. the controller computes the output in real-time) in a Hardware-In-The-Loop-setup with the *Rexroth Simster*, there are two possibilities: either the simulation is forced to run in real-time or the controller has to be adapted to the simulation speed of the simulation environment.

Because the second way has some big advantages, the slowdown of the controller has been realized. One main advantage is the user-friendliness. Main users of this toolchain are engineers like start-up engineers, who shall design a new industrial system and do not have the possibility to use a real-time operating system on their working computer. Additionally, this way is more comfortable, as there are no limits with regard to applicable numerical solve algorithms or the complexity of the model.

To realize the slowdown of the controller, a trigger variable inside the controller application to start the task is necessary, which activates one calculation step

on the controller. After the simulation is progressed by the length of the cycle time, the simulation is stopped and the values of the input variables on the controller are set inside the *IndraWorks* application using MLPI commands. After that, the trigger variable is set to *true*, which starts the calculation of one single step of the controller. At the end of the computation, another variable, which indicates that the computation is finished, is set to *true*. The simulation environment reads the output values from the controller and sets both the trigger variable and the variable indicating the end of the calculation to *false*. These steps are repeated until the end of the simulation time is reached.

In the setup described in this contribution, however, the control algorithm is not implemented in *IndraWorks* and therefore not computed inside the main thread of the controller, but in the separate controller thread running in parallel to the main thread, which makes the situation more complicated. This means, that the program is not controlled via an *IndraWorks* task like in the case discussed before.

### 3.2.3 Establishment of a connection between the different threads

The next challenge is the establishment of the connection between the controller thread and the main thread, because the MLPI commands allow only access to variables and functions inside the *IndraWorks* application running on the PLC. The connection between both threads is realized via a function block inside the *IndraWorks* application. It is possible to link an external implementation to a function block, so this function block has no own implementation.

To ensure that the application will find the missing function implementations, the external implemented functions have to be registered using the MLPI function *mlpiLogicPouExtensionRegister* from the *mlpi-LogicLib*. This function provides the possibility of using C/C++ extensions within the IEC 61131-3 environment *IndraWorks* and describes the mapping between the function block name in *IndraWorks* and the function name in the C/C++ implementation. The variables that shall be exchanged can now be defined as variables inside the function block in the main thread. Then, both the simulation inside *Rexroth Simster* and the controller on the PLC can get access to the variables using MLPI functions as well as read and write the variables. The structure of the communication between the two parallel threads is shown in figure 4.

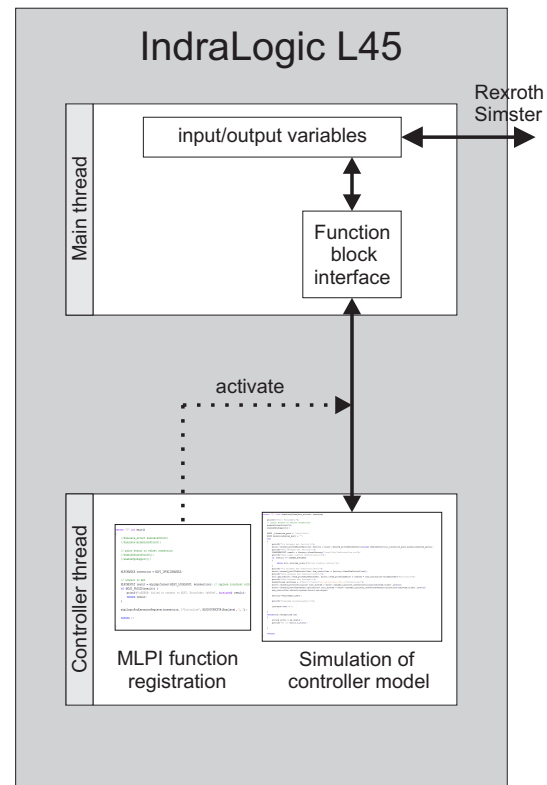

Figure 4: Interface between main thread and controller thread on the hardware controller

After having established the connection between the two threads, the synchronization between the simulation of the system inside *Rexroth Simster* and the controller can be realized analogous to the technique described before. The trigger variable is defined inside the *IndraWorks* application and can be set by both the simulation environment and the controller thread.

### 3.2.4 Initialization of the toolchain

The next aspect to be considered is the initialization of the code execution on the controller. After the compilation of the simulation core and the controller code, all dynamic libraries are available on the internal memory. To start the controller, a main function to manage the code execution (load the libraries in the correct order, call the functions to initialize the solver and the system, start the code execution) is necessary. This function has to be executed before the controller starts, so that all libraries are loaded and all instances of the classes are already initialized. This is the function later called automatically via the function block interface.

### 3.2.5 Resulting workflow for the toolchain

Regarding all the aspects discussed before, the resulting workflow for the toolchain can be derived. Assuming, that the simulation model of the system and the controller inside the simulation environment *Rexroth Simster* already exist, the first step is to compile the simulation core and the controller code for the operating system of the controller (*VxWorks*). Therefore, a new project inside WindRiver Workbench has to be created. The classes inside the simulation core have to be compiled into dynamically linked libraries, which leads to *.out*-files. These *.out*-files have then to be moved to the internal flash card of the Rexroth hardware. This is done using an FTP client. The next step is to register the executable main function containing the initialization of the simulation on the controller (see section 3.2.4). The registration is done using the MLPI function *mlpiPouExtensionRegister*. The syntax is as follows:

```
MLPIRESULT mlpiLogicPouExtensionRegister (
    const MLPIHANDLE connection ,
    const WCHAR16* name ,
    const MLPIPOUFCPTR function ,
    const ULONG signature = 0 ,
    const ULONG version = 0).
```

The first input parameter is the connection handle automatically created when a connection to the hardware via MLPI is established, the second parameter is the name of the POU (Program Organization Unit) in *IndraWorks*, in this case the name of the function block, the third parameter is the function pointer to the C/C++ implementation, while the fourth and fifth describe the signature of the POU interface and the version of the POU library, if implemented within a library, and have not necessarily to be set, as they are predefined with 0 [7].

Now the implementation of the function block interface inside the *IndraWorks* application is made known to the *IndraWorks* application. As the next step, the *IndraWorks* application, which only consists of the function block with the external implementation and the definitions of the variables to be exchanged during the simulation as well as the trigger variable (see section 3.2.2), can also be uploaded to the hardware device (if the *IndraWorks* application is uploaded before the registration of the functions is executed, there will be linker errors for the external implementation of the function block).

The next step is to start the initialization of the controller on the hardware, i.e. to active the func-

tion block. Therefore the task controlling the function block has to be started. This can again be realized via MLPI. The task is defined as *triggered task*, which allows to start the task setting the activation variable to *true*. The start of the main function effects, that all necessary libraries are loaded and the simulation manager is started. Inside the simulation manager, a query is continuously performed, whether the trigger variable to start one calculation step is set or not. For the connection to the hardware device from the *Rexroth Simster* side, a special component is necessary, which has been developed for HiL-tasks (MLPI-Coupler). The component has several inputs and outputs and contains the MLPI-commands to both write the data from the different inputs on the device and read the data from the device and set the values to the outputs of the component. The names of the variables inside *IndraWorks* can be set as component parameters.

The last step is to start the simulation inside *Rexroth Simster*. The cycle time between the exchange of the data can also be set in the MLPICoupler component. The simulation of the system triggers then the simulation on the hardware device. The synchronization between both simulations is realized as described in section 3.2.2.

### 3.2.6 Automation of the toolchain

The toolchain presented in this work is not fully automated until now. In one of the next releases of *Rexroth Simster*, Modelica support will be added to the simulation environment. Until now, an additional Modelica environment is necessary to build up the controller simulation model. In the future, Modelica models can directly be created inside the simulation tool. The code generation is integrated into the simulation core, so that the executable code can directly be generated. This allows a fully automated toolchain, where the controller model can be set up inside the simulation environment and automatically be compiled and sent to the controller. Starting the simulation inside *Rexroth Simster* activates the toolchain (compile the controller model, transfer the code to the controller, load the simulation core libraries, start controller code execution).

## 4 Application on an example system

To verify the functionality, the toolchain is used to develop an appropriate control structure for the control

Figure 5: System model inside Rexroth Simster

of an industrial hydro-mechanical system, namely a single hydraulic axis. This system model is build inside *Rexroth Simster* and simulates the behavior of the hydro-mechanical system. The structure of this simulation model can be seen in figure 5. This model also includes a control loop which has been developed virtually inside the simulation environment.

#### 4.1 Model of the system

The single axis model consists of five sub-blocks, each highlighted in a different color. The light blue block is the HPU (hydraulic pumping unit), i.e. it realizes the oil supply for the hydraulic system and includes the oil tank, a variable pump which is powered by an electric motor. The motor speed is power- and pressure-controlled. Additionally an accumulator is included in the HPU to ensure the oil supply for temporary high demands on oil.

The yellow block shows a generic WRx proportional valve, which limits the volume flow of the hydraulic fluid. Using the input signal port of the valve, the spool position of the valve can be modified. The valve's dynamics is modelled with a PT2-behavior with power limit, the flow is modelled via a characteristic curve depending on the piston stroke ( $Q = f(s)$ ).

The connections between the pump and the valve are modelled by lines including frictional losses. The differential cylinder is modelled inside the grey box. The simulation model of the cylinder considers Stribeck friction (static friction, running friction and Coulomb friction), internal leakage and external leakage. Additionally the cylinder model has two end stops for the piston, which are implemented using momentum conservation (optionally a coefficient of restitution can be specified).

The load is modeled inside the orange sub-box and considers the force resulting from the load mass, the gravity force, the plastic and the elastic deformation. The velocity of the cylinder piston is defined by the user and is available as characteristic curve in the form  $v = f(t)$ . The position profile for the cylinder, which can be obtained through integration of the velocity profile, is shown in figure 6 (blue curve).

#### 4.2 Modeling the controller

To realize the control, the current position of the cylinder piston has to be measured. Therefore, the internal position measuring system of the cylinder, which is included in the cylinder model, is used. As first try for the controller structure a position controller is used. The position controller compares the current position of the piston with the desired position from the profile. The difference (control error) is then multiplied by a gain factor (P-controller). The profile and the controller structure are implemented inside the rose box in figure 5.

#### 4.3 Starting the RCP process

To transfer this controller model to the real hardware device, the toolchain which has been explained in section 3 is used. As numerical solver, the explicit Euler algorithm is used. Note, that the controller model contains an ODE from the integrator component to calculate the position from the velocity profile. For the verification, the results of this HiL-simulation using the developed toolchain are compared with the results produced by a simulation of both the system and the controller inside *Rexroth Simster*. Both results are shown in figure 6, the complete simulation inside *Rexroth Simster* in red, the simulation using the Rapid Control Prototyping toolchain in green.

It can be seen that both curves are very similar, but of course not identical. This is because the controller

Figure 6: Results from the first controller implementation and comparison with the Rexroth Simster simulation

inside *Rexroth Simster* is a continuous controller and gets the position update from the cylinder in every solver time step, while the simulation on the hardware device (like every hardware controller) is updated only in the cycle time of the connection between simulation and hardware. But as the differences are very small, the functionality of the toolchain and the data exchange can definitely be verified.

#### 4.4 Improvements on the controller

If again the V-model of the controller development in figure 1 is considered, the first cycle is now finished. But, if the current result is compared to the desired result, another iteration cycle due to the existing oscillations is necessary. It is clear, that a simple P-controller cannot fulfill the control task. In the second iteration, a velocity feed forward to minimize the gap and an additional control part to minimize the oscillations is integrated into the controller. Therefore, the Modelica code is modified inside the simulation environment. After suitable parameters are determined, the controller structure is again transferred to the IndraControl L45 controller using the toolchain to investigate the functionality on the hardware. Figure 7 shows the result of the improvement of the control algorithm.

Taking a look on the results after this iteration cycle, it can be seen, that the oscillations could be removed. It can be assumed, that the developed controller structure, in general, is suitable to solve the control task in this example (the desired positions are reached without oscillations). In the practice, one or two additional iteration cycle would be performed in order to tune the

parameters to maybe get an even better parameter set, that shifts the current position more towards the desired position to minimize the gap. However, this is skipped at this point.

## 5 Summary and outlook on further investigations

In this work, a toolchain for Rapid Control Prototyping using an industrial Rexroth hardware controller based on open source software is presented. This toolchain allows to reduce commissioning times, avoiding the re-implementation of the controller structure from the simulation environment inside the development environment of the hardware controller. Furthermore, the toolchain is based on open source software. This ensures, that the functionality is independent from software developed by external companies, i.e. additional features can easily be implemented.

The functionality of the toolchain is also verified with an example. Here, the big advantages of Rapid Control Prototyping get visible. The control structure is developed and pre-tested easily inside the simulation environment. To test this control algorithm on the real hardware, until now, it was necessary to re-implement the algorithm. Using the developed toolchain, the re-implementation is no longer necessary, because the final hardware, which is applied later on the real system, is used for the Rapid Control Prototyping Process. The development process consists of several iteration cycles (see 1). In this example, we used three iteration cycles (third one not explicitly shown here), hence, three re-implementations could be saved. In

Figure 7: Results from the second controller implementation and comparison with the Rexroth Simster simulation

more complex systems, of course, the controller structure also gets more complex.

In this contribution, the RCP toolchain is verified virtually in a HiL-setup. In the future, the controller executing the code has to be tested on a real system. Therefore, the *IndraWorks* program has to be adapted. In the HiL-setup, the simulation inside *Rexroth Simster* uses MLPI commands to write the values to the variables in the *IndraWorks* application. If the controller is connected to a real system, the input and output signals are transferred via the input and output ports on the controller. Additional code for the mapping between the I/O ports and the variables is necessary. An important point is the observation of the calculation times. It has to be investigated in the future, how the strict observance of the calculation times can be guaranteed.

Another part of the future work is to fully automate the toolchain, as described in section 3.2.6.

The simulation core can not only be used to simulate controller models to realize Rapid Control Prototyping and couple hardware and software in a Hardware-In-The-Loop simulation. It is also possible to simulate whole system models, which opens the door to many other fields of application. One field of application are alternative control concepts like Model Predictive Control. Model Predictive Control calculates the current control action by solving an optimal control problem at each sampling instant using the current state of the plant as initial state. The cost function of an optimal control problem is optimized subject to different constraints. One main constraint is the system dynamics in the form  $\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}, t)$ . This condition requires the simulation of the system in each optimization step.

## Abstract

The demand to ever increase realism and scope of models routinely exceeds the currently available computing power and thus requires thoughts on improving simulation efficiency. This is especially true for real-time simulations, where fixed timing constraints do not allow to just “wait a bit longer”.

This paper presents a new approach in Modelica that allows a modeler to separate a model into different partitions for which individual solvers can be assigned. In effect, this allows to use multi-rate and multi-method time integration schemes that can contribute to improve the efficiency of a (real-time) simulation.

The first part of the paper discusses basic consideration relating to modular (real-)time integration. Afterwards, the implementation of a convenient Modelica library for the partitioning of physical models is briefly described. Finally, the presented library is used to partition a detailed six degree of freedom robot model for modular simulation. The simulation performance of that partitioned model is compared to the simulation performance achieved by using “conventional” global solvers.

*Keywords: multi-rate / multi-method time integration; simulation; clocked discretized continuous-time partitions.*

## 1 Introduction

Testing the actual embedded systems hardware in processor-in-the-loop (PIL) or hardware-in-the-loop (HIL) setups, usually requires that the “virtual” parts of the overall systems are simulated under real-time constraints. This means that the simulation must run as a hard real-time application that always meets its timing deadlines.

Inputs and outputs of a real-time simulation need to be processed at regular intervals. The length of this

interval is called the *simulation frame time*. The *worst case* computation time needs to be less than the simulation frame time. Explicit fixed-step solvers are appropriate numerical integration routines for real-time simulations. Variable-step solvers are generally not appropriate for two reasons: a) because real-time simulation must normally perform I/O operations at regular intervals, and b) because the flexible number of performed simulation model evaluations impede deterministic prediction of worst case computations times.

Implicit fixed-step solvers are problematic in the context of real-time simulation, because the number of iterations required by implicit methods is theoretically unbounded. However, their numerical properties with regard to integrating *stiff systems*<sup>1</sup> is much more favorable compared to explicit solver methods. When integrating stiff systems using explicit methods, the largest possible step size is severely limited due to stability problems of the integration algorithms. Implicit methods can perform much better in such cases. Because of that, attempts have been made to use implicit methods also in real-time simulation. Elmqvist et al. [5, 4] describe techniques that allow to minimize the number of iteration variables for implicit methods (in some cases the number of iteration variables can be reduced to zero!). These algorithms are available in the commercial tool Dymola for real-time simulation purposes under the umbrella term *inline integration* algorithms. The development of linearly implicit or semi-implicit methods are another noticeable attempt in which implicit solver methods are “approximated” by methods that exhibit a bounded number of worst-case iterations. This improves the suitability of these methods for real-time simulation purposes

Computational resources are finite. As a consequence the computational requirements of the real-time simulation must accommodate with available

<sup>1</sup>Stiff systems typically contain dynamically fast and highly damped components.

hardware resources. If the computational load required for the simulation is too high, the simulation model needs to be adapted in order to meet the timing deadlines. Typical options for improving the computational performance include model simplification, use of more efficient algorithms and operations, or replacing computational intensive subsystems with fast table lookups. Another option is to split the simulation model into subsystems, which can be executed in parallel across multiple processors, or which can be executed with different frame rates. The later option is termed *multiframing* or *multi-rate integration* and can be attractive if some subsystems have significantly longer time constants than others. Details about typical techniques used in the context of real-time simulation can be found in relevant literature, e.g., [7, 3].

The new synchronous language elements extension to Modelica [8, Chapter 16] also provides language primitives that allow the developer to partition models into several parts that can be solved separately by different numerical solver methods. A crucial aspect of the partitioning task is to establish adequate *coupling* mechanism between the separate partitions. Following [6] the term *modular simulation* is used to underline that modular coupling approach.

During the partitioning the developer can take advantage of a-priori system knowledge to improve the performance of the simulation. Partitions can be executed with different frame rates and/or can utilize different numerical integration algorithms. In that way *multi-rate* and *multi-method* integration schemes can be realized. To the knowledge of the authors, this is a rather unique feature in a modeling language for physical systems. However, the suitable preparation of simulation models for multi-rate and multi-method integration is still a non trivial task.

In order to facilitate the preparation of simulation models for multi-rate and multi-method integration schemes a Modelica library named MULTIRATE has been build that wraps necessary methodological and technical knowledge in an easy-to-use framework. The theory behind this library, as well as its technical implementation and application to practical problems will be demonstrated in the following sections.

## 2 Clocked Discretized Continuous-Time

Using the synchronous language elements extension [8, Chapter 16] it is possible to define clocks that associate a continuous-time solver to the equations

associated to that clock. This is illustrated in Figure 1. Line 4 defines a periodic clock with the in-

```

model ClockedDiscretizedContinuousTime
  Real x(start=0), u;
  // 500 ms, no solver:
  Clock clk = Clock(5,10);
  // 500 ms, ExplicitEuler solver:
  Clock clk_solver=
    Clock(clk, "ExplicitEuler");
equation
  // associate clock clk_solver to u:
  u = sample(1.0, clk_solver);
  der(x) = -x + u;
end ClockedDiscretizedContinuousTime;

```

Figure 1: Clocked discretized continuous-time example.

terval 500ms. Line 7 defines a *solver clock* based on the previously defined clock and assigns as solver method "ExplicitEuler". Other methods that are predefined by the language standard are discussed below. Line 10 associates clock `clk_solver` with the variable `u` (by "sampling" the literal constant 1.0 using clock `clk_solver`). Due to clock inference the differential equation in line 11 can be deduced to be also associated with `clk_solver` and therefore the differential equation needs to be solved by the "ExplicitEuler" method with a fixed-step integration step size of 500ms. The corresponding plot of `x` is shown at the right-hand side of Figure 1.

The specification [8, Section 16.8.2] defines the conceptual solution algorithms of the predefined methods (tools may provide support for additional solver methods). Since the following discussion is based on these algorithms the respective part from the specifications is reproduced below in a slightly adapted form<sup>2</sup>.

The solvers are defined with respect to the underlying ordinary differential equation in state space form to which the

<sup>2</sup>Most notably, in contrast to the specification text the solver methods are defined in terms of integrating from clock tick  $t_i$  to  $t_{i+1}$ , instead of from  $t_{i-1}$  to  $t_i$ . This is just a simple index shift. The advantage is, that it allows to present some equations in a slightly more concise and readable form.

Table 1: Predefined solver methods for solver clocks

<i>Solver Method</i>	<i>Solution method</i> (for all methods: $y_i := g(x_i, u_i, t_i)$ )
Explicit-Euler	$x_{i+1} := x_i + h \cdot \dot{x}_i$ $\dot{x}_i := f(x_i, u_i, t_i)$
ExplicitMid-Point2	$x_{i+1} := x_i + h \cdot f(x_i + \frac{1}{2}h \cdot \dot{x}_i, \frac{u_i + u_{i+1}}{2}, t_i + \frac{1}{2}h)$ $\dot{x}_i := f(x_i, u_i, t_i)$
Explicit-Runge-Kutta4	$k_1 := h \cdot \dot{x}_i$ $k_2 := h \cdot f(x_i + \frac{1}{2}k_1, \frac{u_i + u_{i+1}}{2}, t_i + \frac{1}{2}h)$ $k_3 := h \cdot f(x_i + \frac{1}{2}k_2, \frac{u_i + u_{i+1}}{2}, t_i + \frac{1}{2}h)$ $k_4 := h \cdot f(x_i + k_3, u_{i+1}, t_{i+1})$ $x_{i+1} := x_i + \frac{1}{6}(k_1 + 2k_2 + 2k_3 + k_4)$ $\dot{x}_i := f(x_i, u_i, t_i)$
Implicit-Euler	$x_{i+1} := x_i + h \cdot \dot{x}_{i+1}^\dagger$ $\dot{x}_i := f(x_i, u_i, t_i)$
Implicit-Trapezoid	$x_{i+1} := x_i + \frac{1}{2}h \cdot (\dot{x}_i + \dot{x}_{i+1})^\dagger$ $\dot{x}_i := f(x_i, u_i, t_i)$

<sup>†</sup> Equation system with unknowns:  $x_{i+1}, \dot{x}_{i+1}$ .

continuous-time partition can be transformed, at least conceptually ( $t$  is time,  $u(t)$  is the real vector of input variables to the partition,  $x(t)$  is the real vector of continuous-time states, and  $y(t)$  is the real vector of algebraic and/or output variables to other partitions):

$$\begin{aligned}\dot{x} &= f(x, u, t) \\ y &= g(x, u, t)\end{aligned}$$

The solver methods (with exception of "External"<sup>3</sup>) are defined by integrating from clock tick  $t_i$  to clock tick  $t_{i+1}$  and computing the desired variables at  $t_{i+1}$ , with  $h = t_{i+1} - t_i = \text{interval}(u_{i+1})$  and  $x_{i+1} = x(t_{i+1})$ .

Table 1 shows the definitions of the predefined solver methods using the notation from above.

### 3 Multi-Rate

Multi-rate integration can be attractive if some sub-systems have significantly longer time constants than others. This is often the case for multi-domain physical systems since the components of different physical domains often exhibit significant different time constants. A typical example are systems with slow mechanical parts which are controlled by fast electrical

circuits. If an explicit integration method is used, the numerical stability of the whole system depends on the fastest time constant and it is necessary to choose a respective small step size for integration.

The MULTIRATE library doesn't impose limits on the number of partitions with different frame rates that may be executed together. However, for clarity the basic idea of multi-rate integration is demonstrated with two ODE partitions<sup>4</sup> that will be discretized for two different execution rates:

$$\dot{x}_f(t) = f_f(x_f, x_s, t) \quad (1a)$$

$$\dot{x}_s(t) = f_s(x_f, x_s, t) \quad (1b)$$

The sub-index  $f$  stands for the "fast" partition and  $s$  stands for the "slow" partition. Using the ExplicitEuler method from Table 1 for discretization results in a system of recurrence equations of the form:

$$\begin{aligned}x_f(t_i + j \cdot h_f) &= x_f(t_i + (j-1) \cdot h_f) \\ &\quad + h_f \cdot f_f(x_f(t_i + (j-1) \cdot h_f), \\ &\quad x_s(t_i + (j-1) \cdot h), t_i + (j-1) \cdot h) \quad (2a) \\ x_s(t_{i+1}) &= x_s(t_i) + k \cdot h_f \cdot f_s(x_f(t_i), x_s(t_i), t_i) \quad (2b)\end{aligned}$$

where  $k$  and  $j$  are integers,  $k$  is the ratio of the two step sizes,  $j = 1 \dots k$ ,  $h_f$  is the step-size of the fast partition, and  $t_{i+1} - t_i = k \cdot h_f = h_s$  is the step-size of the slow partition.

Note that Equation (2a) does not specify how  $x_s(t_i + (j-1) \cdot h)$  is calculated. Equation (2b) is not defined for intermediate values between  $t_i$  and  $t_{i+1}$ . Therefore, an interpolation or extrapolation scheme needs to be used to estimate the intermediate values.

For real-time simulation the sequence in which the computation of fast and slow frames are interspersed is important. Ledin [7] describes three typical execution schemes. The timing diagram in Figure 2 shows that execution schemes by means of an example where the ratio of the slow and the fast step size,  $k$ , is  $k = 3$ . The three schemes are described briefly below:

1. *Multiframing in a single task with no fast-frame real-time I/O.* The slow frame rate is treated as a "master" frame rate in which the slow frame is executed first, followed by a burst of the  $k$  fast frames. This scheme is only acceptable if the fast frames do not perform any real-time I/O.

<sup>4</sup>In general, partitions in the MULTIRATE library may consist of differential and algebraic equations and the partitions are coupled over designated input and output variables, but this is omitted here in favor of a more succinct presentation of the basic idea of multi-rate integration.

2. *Multiframing in a single task with fast-frame real-time I/O.* The fast frames are executed at fixed intervals of  $h_f$  length. The computations needed in the slow frame are split into several subframes which are interspersed after the fast frame calculations. However, splitting the slow frame into several suitable subframes is rarely a simple thing to do. This is a serious drawback of this method.
3. *Multiframing in a multitasking environment with rate monotonic scheduling (RMS).* In this case the scheduler will give CPU access to the task with the higher priority (computation of fast frames) and interrupt the lower priority task (computation of slow frames) until the higher priority task has finished its computations. During the times in which the higher priority task is idle, the CPU access is given back to the lower priority task to resume its computations. No (manual) splitting into subframes is needed which is a huge advantage compared to the previous method.

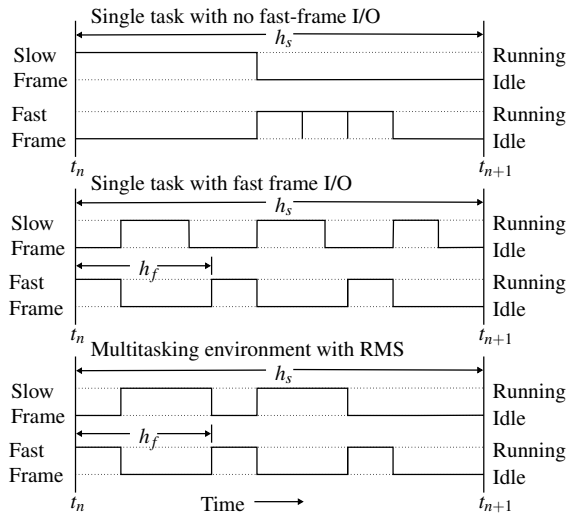

Figure 2: Three different multiframing schemes for real-time simulation.

## 4 Multi-Method

*Multi-method integration* (also called *mixed-mode integration*) is yet another option to improve the execution performance of (real-time) simulation. In contrast to multi-rate integration that uses different integration step sizes for distinct partitions, multi-method integration uses different integration methods for distinct partitions. Similarly to multi-rate integration, multi-

method integration can be attractive if some partitions have significantly longer time constants than others.

A typical scenario is to split a system into fast parts and slow parts and use an implicit integration method for the fast parts and an explicit integration method for the slow parts. Schiela and Olsson [11] describe such a mixed-mode integration scheme (using explicit and implicit Euler methods) in which they employ an automatic partitioning approach based on linearization and eigenvalue analysis. This disburdens the developer from partitioning the system. However, if a system is highly nonlinear, inspecting eigenvalues becomes questionable since the eigenvalues of the linearized system move around with time. A user controlled partitioning, leveraging a-priori system knowledge, can be more adequate and effective in such cases.

Similar to multi-rate integration, the basic idea of multi-method integration is demonstrated on the basis of two ODE partitions in the form of equation system (1). Using the `ImplicitEuler` method from Table 1 for the “fast” partition and the `ExplicitEuler` method for the “slow” partition results in recurrence equations of the form:

$$x_s(t_{i+1}) = x_s(t_i) + h \cdot f_s(x_f(t_i), x_s(t_i), t_i) \quad (3a)$$

$$x_f(t_{i+1}) = x_f(t_i) + h \cdot f_f(x_f(t_{i+1}), x_s(t_{i+1}), t_{i+1}) \quad (3b)$$

where  $h = t_{i+1} - t_i$  is the integration step-size. At first,  $x_s(t_{i+1})$  is computed using the explicit Euler method. This value is afterwards used to compute  $x_f(t_{i+1})$  using the implicit Euler method.

The `MULTIRATE` library allows to combine any of the solver methods listed in Table 1. Note that it is easily possible to combine multi-rate and multi-method integration within the framework of the `MULTIRATE` library. This allows to exceed the benefits compared to applying the methods separately.

## 5 Partition Coupling

An important aspect when applying multi-rate and multi-method integration is the coupling between the involved partitions. In the context of the framework provided by the `MULTIRATE` library the coupling scheme of Figure 3 depicts the basic idea (liberally abstracting from the details). Note that although the coupling is discussed by considering the special case of two coupled partitions, the basic principles carry over to the general case of  $n$  partitions.

Partition 1 and 2 may be discretized by using one of the solver methods defined in Table 1. Different solver

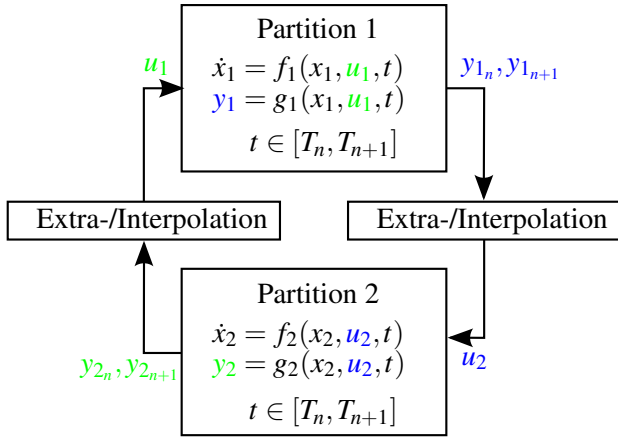

Figure 3: Coupling of two partitions. Communication takes place at discrete time instants  $t = T_0, T_1, \dots, T_k$ . Depending on the applied coupling scheme the approximation of the coupling terms  $u_1, u_2$  can be based on interpolation (if  $y_{1n+1}$ , or respectively  $y_{2n+1}$  is available) or it must be based on extrapolation.

methods, as well as different step sizes can be used as long as the ratio of the step sizes is an integer.

Data exchange between clocked discretized continuous-time partitions is only possible at clock ticks. Therefore, the clock ticks of the slower partition determine the discrete time grid in which data is exchanged between the two partitions. This is quite similar to the situation encountered in co-simulation scenarios, in which the communication and data exchange between two distinct systems is restricted to discrete synchronization points  $T_n$ .

However, in contrast to co-simulation the modular integration considered in the MULTIRATE framework has some distinctive characteristics:

- It inherits the characteristics of the synchronous model of computation that has been introduced in the “Synchronous Language Elements” extension in Modelica 3.3 [8, Chapter 16]. This has the advantage that the formal model of various coupling schemes can be expressed in a high-level, declarative manner which is close to the underlying conceptual mathematical model. However, the drawback is that optimizations that require a more low-level control can not be realized.
- Modelica uses *acausal* connectors to assemble models of physical components. However, the coupling of partitions according to Figure 3 requires *causal* data-flow. It is not obvious how convenient and effective coupling schemes can be

realized when a model should be partitioned at acausal connectors.

## 5.1 Mathematical Model

For the further analysis more detailed mathematical models than the one indicated in Figure 3 are proposed. As before, the discussion is based on two partitions, but carries over to more general settings involving  $n$  partitions.

Figure 4 depicts a continuous-time domain model for two coupled partitions, including inputs  $(u_1, u_2)$  and outputs  $(y_1, y_2)$  due to real-time I/O hardware devices. The dynamics of the coupled partitions are modeled as differential-algebraic equations (DAEs) in autonomous semi-explicit form

$$\dot{x}_1 = f_1(x_1(t), \tilde{x}_2(t), z_1(t), \tilde{z}_2(t), \tilde{u}_1(t)) \quad (4a)$$

$$0 = \gamma_1(x_1(t), \tilde{x}_2(t), z_1(t), \tilde{z}_2(t), \tilde{u}_1(t)) \quad (4b)$$

$$y_1 = g_1(x_1(t), \tilde{x}_2(t), z_1(t), \tilde{z}_2(t), \tilde{u}_1(t)) \quad (4c)$$

$$\dot{x}_2 = f_2(\tilde{x}_1(t), x_2(t), \tilde{z}_1(t), z_2(t), \tilde{u}_2(t)) \quad (4d)$$

$$0 = \gamma_2(\tilde{x}_1(t), x_2(t), \tilde{z}_1(t), z_2(t), \tilde{u}_2(t)) \quad (4e)$$

$$y_2 = g_2(\tilde{x}_1(t), x_2(t), \tilde{z}_1(t), z_2(t), \tilde{u}_2(t)) \quad (4f)$$

with differential variables  $x_i \in \mathbb{R}^{n_{x_i}}$ , algebraic variables  $z_i \in \mathbb{R}^{n_{z_i}}$ , (real-time) inputs  $u_i \in \mathbb{R}^{n_{u_i}}$ , and outputs  $y_i \in \mathbb{R}^{n_{y_i}}$  where  $n_{x_i}, n_{z_i}, n_{u_i}, n_{y_i} \in \mathbb{N}$  and consistent initial conditions  $x_i(t_0) = x_{i,0}$ ,  $z_i(t_0) = z_{i,0}$ . The (continuous-time) variables with tilde,  $\tilde{x}_i, \tilde{z}_i, \tilde{u}_i$  are reconstructed from a number of  $m \geq 1$  sampled (discrete-time) values of the variables without tilde of the same name by means of extrapolation or interpolation using a “reconstruction” operator denoted  $\Psi$

$$\tilde{x}_i(t), \tilde{z}_i(t) = \Psi_i(\chi_i, \zeta_i)(t) \quad t \in [T_n, T_{n+1}] \quad (4g)$$

$$\tilde{u}_i(t) = \Psi_{u_i}(v_i)(t) \quad (4h)$$

where  $\chi_i, \zeta_i, v_i$  are sampled at time instants  $t_k \in (T_{n-m}, T_n]$  (extrapolation), or  $t_k \in (T_{n+1-m}, T_{n+1}]$  (interpolation)

$$\chi_{ik}, \zeta_{ik} = x_i(T_k), z_i(T_k) \quad k = 1 \dots k_i, \quad T_k < T_{k+1},$$

$$k_i \in \mathbb{N}, \quad \chi_i \in \mathbb{R}^{n_{x_i} \times k_i}, \quad \zeta_i \in \mathbb{R}^{n_{z_i} \times k_i}$$

$$v_{ik} = u_i(T_k) \quad k = 1 \dots k_{u_i}, \quad T_k < T_{k+1},$$

$$k_{u_i} \in \mathbb{N}, \quad v_i \in \mathbb{R}^{n_{u_i} \times k_{u_i}}.$$

The operator  $\Psi$  is loosely borrowed from the mathematical framework described in [12, p. 1495], where it is defined as extrapolation operator. The definition there is mathematically more technical and rigorous than considered necessary for this work.

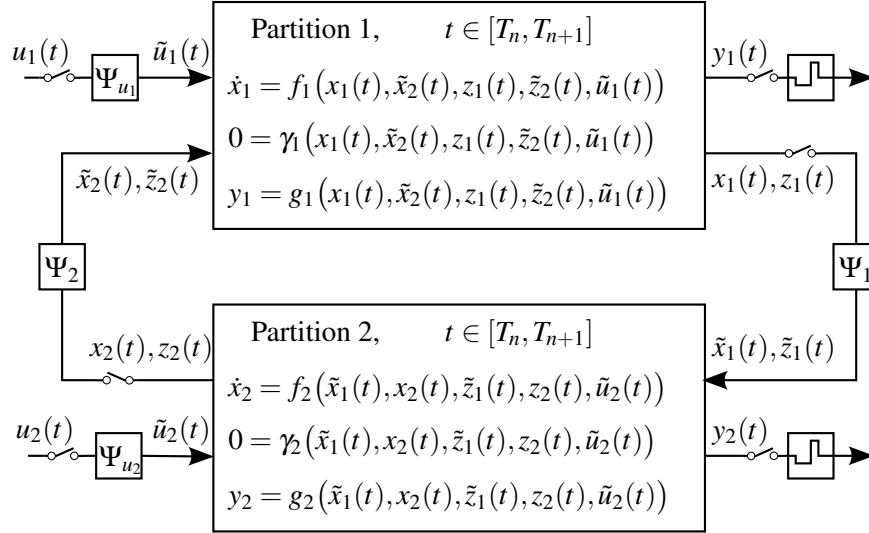

Figure 4: Illustration of the used continuous-time domain mathematical model for partition coupling, including external real-time I/O ( $u_1, u_2, y_1, y_2$ ). The inputs to the partitions are first sampled at discrete time instants  $t = T_0, T_1, \dots, T_k$ , subsequently the operators  $\Psi_i$  are applied to the (time-discrete) signals in order to provide extrapolated/interpolated continuous-time signals during a period of continuous-time system evolution ( $t \in [T_n, T_{n+1}]$ ).

Data exchange between partitions and the update of coupling terms is restricted to the time-discrete synchronization points  $t = T_0, T_1, \dots, T_k$ . In co-simulation the steps from  $T_n \rightarrow T_{n+1}$  are referred to as *macro steps*. The union of all macro-time steps is a macro-time grid where the partitions update their coupling terms. Generally, the real-time inputs and outputs of the respective partitions may be sampled at discrete time instants that are different to the macro-time grid instants. During a macro step  $T_n \rightarrow T_{n+1}$  the dynamics of the partitions evolve according to the governing DAE using extrapolated (or interpolated) data. Note that  $\tilde{x}_i, \tilde{z}_i, \tilde{u}_i$  are continuous in each macro step  $T_n \rightarrow T_{n+1}$  but may have jump discontinuities at the synchronization points  $T_n$ .

Since this work is concerned with real-time simulation, it is natural to consider only equidistant macro-time grids with constant macro-step size  $h = (T_{n+1} - T_n)$ . Moreover, the utilized synchronous framework in conjunction with the discretization formula given in Table 1 suggests to describe the coupling within a (discrete-time) recurrence equation framework. The step-sizes  $h_i$  of the two partitions may differ, but the ratio between the slower and faster period must be an integer multiple. Without loss of generality assume that  $h_1$  is the faster partition and denote  $N = h_2/h_1$  as the frame ratio. The partitions are synchronized at the discretization points ( $\equiv$  macro-time grid)

$$t = k \cdot N \cdot h_1 = k \cdot h_2 = k \cdot h, k \in \mathbb{N}. \quad (5)$$

At these points the equations of both partitions have to be fulfilled concurrently (synchronous model of computation).

The overall discretized system equations can now be described in terms of the faster sampling period  $h = h_1$ , further also denoted as micro-time step. The precise time dependencies, i.e., at which instant  $t_i = i \cdot h_1$  on the micro-time grid coupling variables from time instant  $t_{i \leq j}$  are required depend on the utilized discretization method. Table 2 shows the dependencies for the solver methods supported by the Modelica standard. The important characteristics to be observed are:

1. Algebraic equations always, regardless of the utilized solver method, require the variable values at the current time instant on the micro/macro-time grid.
2. For state integration using `ExplicitEuler` coupling variable values and state variable values from previous activation times are sufficient.
3. The other two explicit methods require coupling variable values from the *current* time instant (due to the occurrence of term  $\frac{u_i + u_{i+1}}{2}$  in the defining equations in Table 1!)
4. The implicit methods require coupling variable values and state variable values from the current time instant.

Table 2: Coupled variables time dependencies after discretization

<i>Solver Method</i>	<i>Time instant dependencies</i>
	For all methods: $h_1$ is the step-size of the fast partition, and $t_{i+1} - t_i = N \cdot h_1 = h_2 = h$ is the step-size of the slow partition, $N, j \in \mathbb{N}, N = h_2/h_1, j = 1 \dots N$ . $\tilde{x}_{1,i}, \tilde{z}_{1,i}, \tilde{x}_{2,i}, \tilde{z}_{2,i}$ are approximated from $x_{1,i}, z_{1,i}, x_{2,i}, z_{2,i}$ by a suitable extrapolation method. Time dependencies in the algebraic equations are always:
	$0 = \gamma_1(x_{1,iN+j}, \tilde{x}_{2,iN+j}, z_{1,iN+j}, \tilde{z}_{2,iN+j})$ $0 = \gamma_2(\tilde{x}_{1,(i+1)N}, x_{2,(i+1)N}, \tilde{z}_{1,(i+1)N}, z_{2,(i+1)N})$
Explicit-Euler	$x_{1,iN+j} = f_1(x_{1,iN+j-1}, \tilde{x}_{2,iN+j-1}, z_{1,iN+j-1}, \tilde{z}_{2,iN+j-1})$ $x_{2,(i+1)N} = f_2(\tilde{x}_{1,iN}, x_{2,iN}, \tilde{z}_{1,iN}, z_{2,iN})$
Explicit-MidPoint2 / RungeKutta4	$x_{1,iN+j} = f_1(x_{1,iN+j-1}, \tilde{x}_{2,iN+j}, z_{1,iN+j-1}, \tilde{z}_{2,iN+j})$ $x_{2,(i+1)N} = f_2(\tilde{x}_{1,(i+1)N}, x_{2,iN}, \tilde{z}_{1,(i+1)N}, z_{2,iN})$
Implicit-Euler / Trapezoid	$x_{1,iN+j} = f_1(x_{1,iN+j}, \tilde{x}_{2,iN+j}, z_{1,iN+j}, \tilde{z}_{2,iN+j})$ $x_{2,(i+1)N} = f_2(\tilde{x}_{1,(i+1)N}, x_{2,(i+1)N}, \tilde{z}_{1,(i+1)N}, z_{2,(i+1)N})$

This has the following consequences for clocked discretized continuous-time partitions that are coupled within Modelica’s synchronous computation framework:

- In the general case, there is no scheduling of  $\gamma_1$  and  $\gamma_2$ , that satisfies reciprocal data dependencies without resorting to extrapolation from previous values.
- State integration using **ExplicitEuler** allows to use  $\tilde{x}_{1,iN}, \tilde{z}_{1,iN} = x_{1,iN}, z_{1,iN}$  (no extrapolation needed, since values already available at  $t_{i+1}N$ ). However,  $\tilde{x}_{2,iN+j-1}, \tilde{z}_{2,iN+j-1}$  need extrapolation for  $j > 1$ . Scheduling of  $f_1, f_2$  at the macro-time grid is always possible, since only past values are required at these points.
- For state integration using the remaining explicit and implicit methods, there is no scheduling of  $f_1$  and  $f_2$  that satisfies reciprocal data dependencies in the general case without resorting to extrapolation from previous values.

Note that in Modelica’s synchronous computation framework it is not allowed to have algebraic loops *spanning* clocked discretized continuous-time partitions (however, it is allowed to have algebraic loops *within* a partition!). Therefore, there must be a sorting for the coupling equations at macro-time grid points that allows to evaluate them in a sequential order that satisfies data dependencies.

The previous discussion already allows to identify some of the consequences when using the synchronous framework for partition coupling:

- A staggered method (Gauss-Seidel scheme) that would first integrate the slow partition, extrapolating the inputs from the coupled (fast) partition, and after that integrate the fast partition, *interpolating* from the results of the slow partition, is not feasible. This is because within the synchronous framework new values are accessible only at the points at time where they are *valid* and not directly after they have been computed. Also, it is not possible for the modeler to directly influence the sequence of calculations. This is at the discretion of the simulation tool that will only guarantee to respect data flow dependencies.
- Nevertheless, an execution scheme similar to the “*Single task with no fast-frame real-time I/O*” depicted in Figure 2 is feasible, however, the interpolation of coupling variables during execution of the fast partitions is not possible (extrapolation is required).
- The synchronous model of computation makes the abstractions that equations at time instants are evaluated instantaneously. However, in reality, computation takes time. From a real-time I/O timing perspective it is desirable that the simulation time instants of inputs and outputs closely fit the real-time instants. For that reason, dedicated real-time integrators are typically designed to require only past inputs for the integration up to the current time instant. This allows to compute the output values required at real-time instants  $t = T_n$  during a computational period scheduled at  $t < T_n$ . This computational timing details are beyond the scope of the Modelica specification. However, observe that all solvers specified in Table 1 (except **ExplicitEuler**) require the (real-time) inputs at  $t = T_n$  in order to compute the outputs at  $t = T_n$ . Therefore, the real-time outputs will be inevitable afflicted with a (potentially considerable) computational delay ( $t_{\text{outputs}} = T_n + t_{\text{delay}}$ ).

Obviously, it will often be desirable to keep at least  $t_{\text{delay}}$  as small as possible. For the “*Single task with no fast-frame real-time I/O*” scenario it is therefore advisable to schedule the computation of the slow frame’s real-time outputs before executing the fast frames (just as depicted in Figure 2)<sup>5</sup>.

- Parallel coupling methods using solely extrapolated coupling terms (Jacobi-scheme) can be realized within the available synchronous framework. Therefore, parallel execution of frames as depicted at the bottom of Figure 2 should be feasible. This is expected to be particularly attractive if a simulation can benefit from multi-core hardware and distribute the computational load on the available cores<sup>6</sup>.
- Some of the solver methods in Table 1 are *multi-pass* methods<sup>7</sup>, i.e., they require several “intermediate” evaluation of  $f(\cdot)$  during integration. Since communication within the synchronous framework can only occur at clock ticks, the needed intermediate values of the inputs  $u$  are computed by interpolation. The alternative to actually acquire (real-time) samples of  $u$  for this intermediate evaluations is not possible in the current framework. However, it should be noted that for dedicated real-time integrators the use of intermediate input samples is typically considered [1, 9].

## 5.2 Partition Coupling at Acausal Connectors

In Figures 3 and 4 the coupling of partitions is accomplished by causal (directed) dataflow. However, physical modeling in Modelica relies on acausal connectors. It is not obvious how to accomplish partition coupling at the boundary of acausal connectors.

The following discussion is based on couplings at the boundary of rotational mechanical connectors from the Modelica Standard Library. However, the

presented principles are easily transferable to other physical connectors.

Consider the academic example model in Figure 5 and assume the model shall be partitioned somewhere between the inertias  $J_1$  and  $J_2$ .

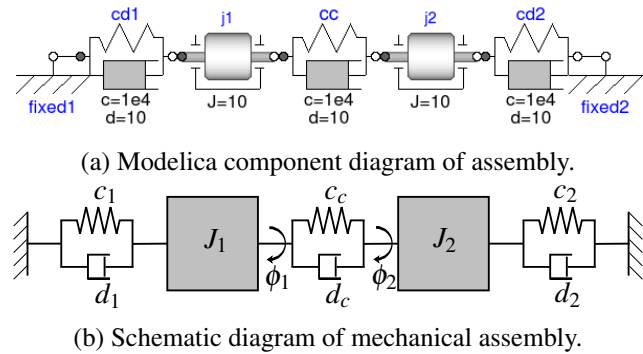

Figure 5: The example model: a linear 2-DOF oscillator.

Figure 6 shows two common approaches to partition the model for modular integration [2]:

**Force/displacement coupling** Partition  $P_1$  provides the cut torque at its boundary as output which is the input to partition  $P_2$ . Conversely, partition  $P_2$  provides the displacement at its boundary as output which in turn is the input to partition  $P_1$  (Figure 6a).

**Displacement/Displacement coupling** The coupling force element of  $S_1$  is duplicated in  $S_2$ . The two partitions are coupled by the displacements of  $S_1$  and  $S_2$  (Figure 6b).

## 5.3 Implementation in Modelica

The Modelica MULTIRATE library provides convenient building blocks for partitioning a model for multi-rate and multi-method simulation. It is implemented on top of the synchronous language elements, partly reusing functionality provided by the MODELICA\_SYNCHRONOUS library [10].

### 5.3.1 Force/Displacement Coupling

The component diagram in Figure 7a shows the oscillator from Figure 5a in a *force/displacement* coupling configuration. The coupling component subSample1 is an instance of the SubSampleForceDisp class from the MULTIRATE library. The SubSampleForceDisp class provides a few parameters to modify the coupling characteristics, namely inferFactor to define that the

<sup>5</sup>The Modelica standard doesn’t provide any possibility for a modeler to control the scheduling of computations. Therefore, a reasonable scheduling of real-time I/O can be seen as an implementation quality trait of a Modelica tool.

<sup>6</sup>However, the Modelica standard doesn’t provide any means for a modeler to control whether computations are parallelized. At the time of writing this article the authors are not aware of any Modelica tool that supports parallelization of clocked partitions.

<sup>7</sup>Namely, the solver methods ExplicitMidPoint2 and ExplicitRungeKutta4.

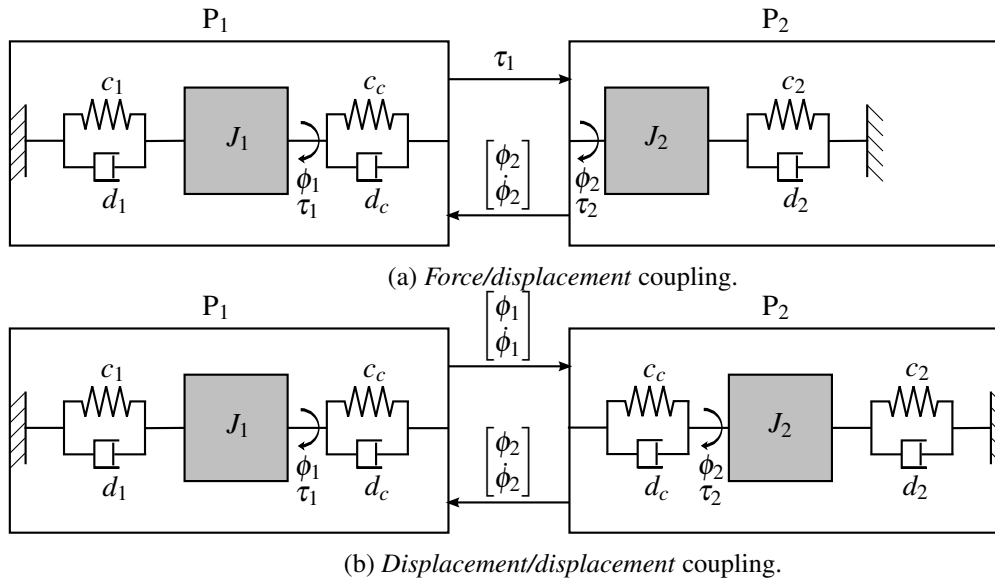

Figure 6: Partitioning the example model.

tool shall determine the sub-sample factor by clock inference. Otherwise, the sub-sample factor can be entered manually. Efficient polynomial extrapolation of arbitrary degree  $nP$  is supported for extrapolating values stemming from the slow partition during execution of the fast partition<sup>8</sup>. With default settings the output of the fast partition will be delayed one clock tick, however parameter `useDirectFeedthrough` allows to avoid that delay. The delay is necessary if both partitions need at macro-time steps  $t = iN$  the current coupling values of the respective other partition. As has been discussed in Section 5.1 this reciprocal data dependencies lead to illegal algebraic loops spanning the coupled partitions. Note that if at least one of the partitions uses `ExplicitEuler` as solver method, a scheduling without algebraic loops may become feasible and `useDirectFeedthrough` may be set to **true**.

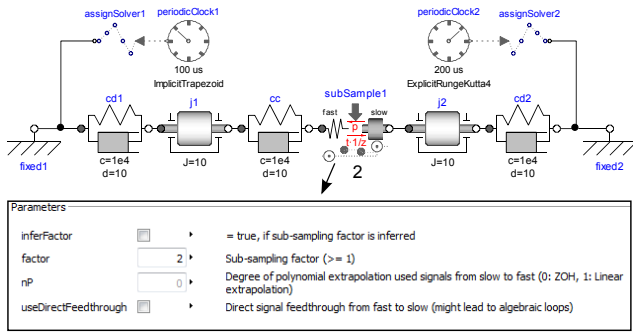

The design of the icon of the `SubSampleForceDisp` class gives a visual clue regarding the intended placement within a model. The component at the left hand side receives a displacement ( $\phi$  and derivatives of  $\phi$ ), and needs to provide a torque  $\tau$ . This is typical for spring like elements. The right hand side component receives a torque and reacts with a displacement. This is typical for inertia like components. The sub-

sampling factor is displayed at the bottom of the icon (provided that `inferFactor=false`).

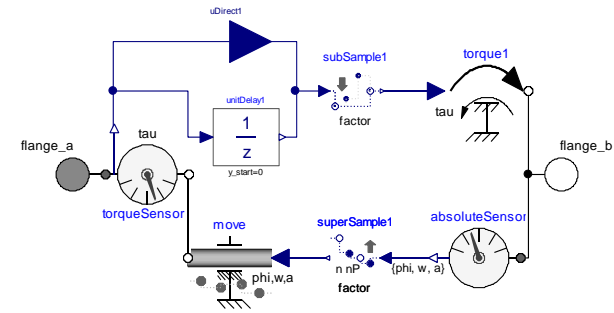

The internal structure of the `SubSampleForceDisp` class is depicted in Figure 7b. The parallel branches with component `uDirect1` and `unitDelay1`<sup>9</sup> are conditional branches. Their activation is mutually exclusive and depends on the value of the parameter `useDirectFeedthrough`. The `subSample1` block wraps Modelica's `subSample(...)` operator, which performs fast-to-slow rate transitions. Component `absoluteSensor` returns an array with the displacement variables  $\{\phi, \dot{\phi}, \ddot{\phi}\}$ . Upsampling and (polynomial) extrapolation of the variables is performed by the `superSample1` block. Since  $\phi$  is a discrete-time (sampled) signal (see Figure 4), it carries no information about its derivatives. It is the task of component `move` to force the movement of flange `flange_a` according to signals  $\phi$ ,  $\dot{\phi}$  and  $\ddot{\phi}$ . In the implementation smoothness information of  $\phi$  is recovered at the sampling points by using the sampled values of  $\dot{\phi}$  and  $\ddot{\phi}$  and setting the recovered signal equal to `flange_a.phi`. This is accomplished by using the derivative annotation as described in [8, Section 17.7, “Declaring Derivatives of Functions”]. Components `torqueSensor` and `torque1` are from the Modelica Standard Library.

<sup>8</sup>Note that  $nP=0$  is equivalent to holding the value constant and  $nP=1$  is equivalent to linear extrapolation. Moreover, while increasing the order of extrapolation may result in improved numerical stability and accuracy in some applications it may also deteriorate numerical stability (see [2] for comprehensive numerical experiments regarding extrapolation and interpolation of coupling signals in co-simulation scenarios). In many cases,  $nP=0$  or  $nP=1$  seems to be a good choice.

<sup>9</sup>The `unitDelay1` block wraps the `previous` operator. According to the current specification [8, Section 16.8.1] the use of `previous` within a clocked discretized continuous-time partition is forbidden. However, the Dymola 2014 FD01 tool used for this work is more lenient and allows it. This is a desirable feature in order to enable the described implementation.

(a) Example model using a *force/displacement* coupling in a multi-rate and multi-method configuration. The coupling component subSample1 is an instance of class SubSampleForceDisp from the MULTIRATE library.

(b) Component composition diagram of class SubSampleForceDisp. This class implements the *force/displacement* coupling.

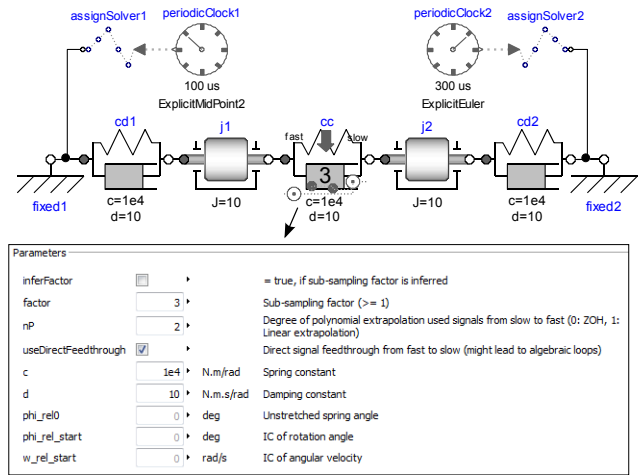

Figure 7: *Force/displacement* coupling using the MULTIRATE library.

### 5.3.2 Displacement/Displacement Coupling

The component diagram in Figure 8a shows the oscillator in a *displacement/displacement* coupling configuration. The component cc is an instance of class SubSampleDispDisp from the MULTIRATE library. It constitutes both: the dynamic equations of motion for the spring/damper element and the partition coupling equations.

The upper part of parameters of the SubSampleDispDisp class is identical to the parameters provided by the SubSampleForceDisp class. The lower part provides parametrization for the spring/damper element.

The internal structure of the SubSampleForceDisp class is depicted in Figure 8b. Note that the dynamic equations for the spring/damper element are duplicated: while component springDamper1 is assigned to the slow partition, springDamper2 is assigned to the fast partition. This “overlapping” integration often leads to more favorable numerical stability properties (see Busch [2]). Aside from this, the components appearing in Figure 8b are already known from Fig-

(a) Example model using *displacement/displacement* coupling in a multi-rate and multi-method configuration.

(b) Implementation of *displacement/displacement* coupling class.

Figure 8: *Displacement/displacement* coupling using the MULTIRATE-library.

ure 7b.

While this section described the partitioning at the example of 1-dimensional, rotational mechanics, it is needless to say that the basic approach carries over to other physical domains. Furthermore, the mindful reader may miss a SubSampleDispForce class. That class was omitted, since it basically results by swapping and adapting respective components in Figure 7b.

## 6 Application to a 6-DOF Robot Model

In order to understand whether the partitioning is suitable for “real-world” systems with considerable complexity, the RobotR3 example (a detailed model of a robot with six degrees of freedom) from the MultiBody package of the Modelica Standard Library (MSL) was adapted and partitioned into three parts (see Figure 9):

1. “**clockControl**” partition. The partition consists of a clocked discrete-time path planning component and clocked discrete-time P-PI cas-

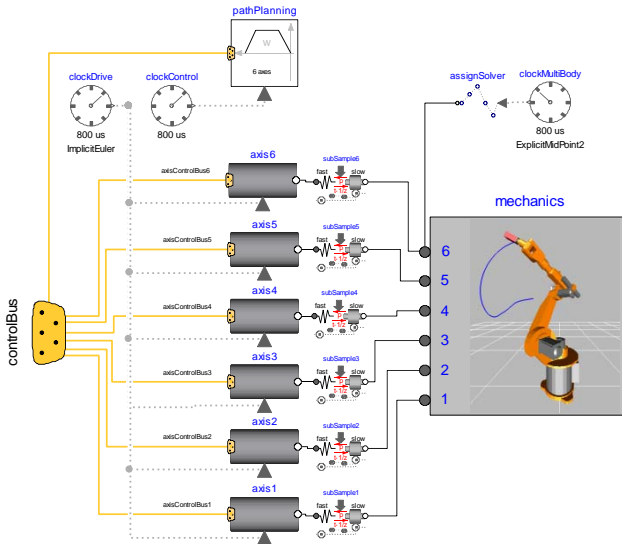

Figure 9: 6-DOF robot example adapted from the RobotR3 example of the multi-body package of the MSL.

cade controllers for the six axes (inner PI-controllers to control the motor speeds, and outer P-controllers to control the motor positions). Therefore, the continuous-time controllers and the path planning component from the original RobotR3 example were replaced by a discrete-time (digital) implementation. The sample period of that partition is set to  $800 \mu\text{s}$ .

2. **“clockDrive” partition.** The remaining parts in each axis (motor including current controller and the gearbox including gear elasticity and bearing friction) are combined into a clocked discretized continuous-time partition. The steady-state initialization found in the original RobotR3 example was removed since the initialization of clocked partitions differs from the standard scheme of initialization in Modelica [8, Section 16.9, “16.9 Initialization of Clocked Partitions”]. Instead, compatible initial values have been set at appropriate places. “ImplicitEuler” with a step size of  $800 \mu\text{s}$  is used as solver method.
3. **“clockMultiBody” partition.** Except for setting compatible initial values, the multi-body part is identical to the original RobotR3 model. “ExplicitMidPoint2”, also with a step size of  $800 \mu\text{s}$ , is used as solver method.

Partitions “clockDrive” and “clockMultiBody” are coupled at the mechanical flanges connecting the axes

with the mechanics multi-body system by *force/displacement* components with constant extrapolation ( $nP=0$ ) and no direct feedthrough.

The simulation performance using the solver clocks was compared against simulations performed on the same model (using various solvers), but without using coupled clocked discretized continuous-time partitions (see Figure 10).

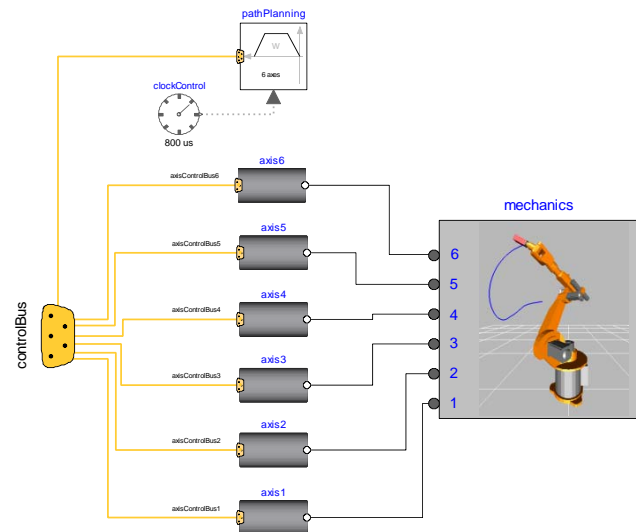

Figure 10: Comparison model: 6-DOF robot example without coupled clocked discretized continuous-time partitions.

The numerical experiment is conducted on a notebook with an Intel Core 2 Duo CPU P9700 @ 2.8 GHz and 4.0 GB of RAM. The simulation tool is Dymola 2014 FD01 running on a 64-bit Microsoft Windows 7 operating system.

The reference simulation result is obtained by simulation of the comparison model (Figure 10) using DASSL as integrator. The solver parameter “Tolerance” is set to 0.0001 for all simulation runs. The simulation interval is always set to  $[0, 2]$  seconds. The step size of the tested solver methods is iteratively increased until either integration fails (which for the considered model typically means that too large residuals appear while solving (nonlinear) systems of equations), or the simulation result deviates considerably from the DASSL reference solution.

The decision whether a result deviates considerable from the reference solution is made by two criteria: a) visual inspection of the trajectory of the load at the robot arm tip, and b) deviation of the trajectory to the

reference solution defined by the norms

$$E_2 = \sqrt{\int_{t_0}^{t_e} e_r(t)^2 dt} \quad (6a)$$

$$E_\infty = \sup_{t \geq t_0} (e_r(t)) \quad (6b)$$

where  $t_0$  is the simulation start time,  $t_e$  is the simulation stop time and

$$e_r(t) = \frac{\|r(t) - r_{\text{DASSL}}(t)\|}{\|r_{\text{DASSL}}(t)\|} \quad r, r_{\text{DASSL}} \in \mathbb{R}^3$$

provides a relative error measurement by relating the distance between the obtained solution  $r(t)$  and the reference solution  $r_{\text{DASSL}}(t)$  to the magnitude of the vector  $r_{\text{DASSL}}(t)$ . For the actual computation of  $E_2$  and  $E_\infty$ , (6a) and (6b) are numerically evaluated over an uniformly spaced grid with spacing  $\Delta t = 0.0008$ . Therefore, the integral in (6a) is approximated by numerical summation.

In Figure 11 the DASSL reference solution is compared with the result when simulating the coupled partitions model of Figure 9 and the result when simulating the comparison model of Figure 10 with an inline implicit Euler solver.

Figure 11a shows the first Cartesian coordinate of the trajectory of the robot arm tip. It can be observed that the solution computed by the implicit Euler solver with fixed step size 0.0016 s diverges considerably at the end of the simulation run. Examining the evolution of the norms  $E_2$  and  $E_\infty$  confirms that observation (see Figure 11b). At  $t = 2$  s the relative error of the implicit Euler solution compared to the DASSL reference is about 3%.

Beside using the DASSL integrator, various real-time inline integrators provided by the tool Dymola [5] were tested with the comparison model. Table 3 summarizes the results obtained by that simulation experiments and contrasts them to the result obtained by simulation of the coupled partitions model of Figure 9.

The *inline implicit Euler* solver displayed the best performance of the tested “conventional” solvers. However, for this scenario it was possible to even outperform that solver by a factor of about 2.9 (at comparable accuracy to the reference solution) by using a coupling of clocked discretized continuous-time partitions in combination with judiciously selected solver methods.

(a) Trajectory of the first Cartesian coordinate of the robot arm tip.

(b) Evolution of the norms  $E_2$  and  $E_\infty$  over the simulation time.

Figure 11: Simulation results of coupled partition approach and implicit Euler solver (step size 0.0016 s) compared to the DASSL reference solution.

## 7 Conclusions

This paper presented a new approach in Modelica that allows a modeler to separate a model into different partitions for which individual solvers can be assigned. This effectively allows multi-rate and multi-method time integration schemes that can improve simulation efficiency in certain cases. Additionally, there is a potential to execute the partitions in parallel to gain further simulation speedups. However, this is not supported by currently available tools.

The approach is based on *clocked discretized continuous-time partitions*, a concept that was introduced as part of the synchronous language elements extension into the Modelica 3.3 language standard. However, until now it has not been applied in the context considered in this article.

The article started with a formal description of

Table 3: Comparison of solver methods

Solver	Step size (s)	CPU-time for integration (s)	$E_2$	$E_\infty$
DASSL		10.8	0	0
<b>Coupled partitions</b>	$2 \times \mathbf{0.0008}$	<b>0.7</b>	0.0014	0.0019
<b>Inline implicit Euler</b>	<b>0.0008</b>	<b>2.0</b>	0.0058	0.0081
<i>Inline implicit Euler (considerable deviation)</i>	<i>0.0016</i>	<i>(1.2)</i>	0.0207	0.0313
Inline trapezoidal	0.0008	2.1	0.0059	0.0082
<i>Inline trapezoidal (considerable deviation)</i>	<i>0.0016</i>	<i>(1.3)</i>	0.0208	0.0313
Inline explicit Euler	0.00002	2.3	0.0009	0.0017
<i>Inline explicit Euler</i>	<i>0.00004</i>	<i>(Failed)</i>		
Mixed explicit/implicit Euler	0.0004	3.5	0.0004	0.0008
<i>Mixed explicit/implicit Euler</i>	<i>0.0008</i>	<i>(Failed)</i>		
Inline explicit RK 4	0.00002	8.6	0.0004	0.0009
<i>Inline explicit RK 4</i>	<i>0.00004</i>	<i>(Failed)</i>		

the mathematical prerequisites of coupling partitions within the synchronous language elements framework with special regard to timing requirements inherent to real-time simulations. In the following, the implementation of a Modelica library for the partitioning of physical models, denoted as MULTIRATE library, was sketched out. Finally, elements of that library were used to partition a detailed robot model and the simulation performance of that partitioned model was compared to “conventional” inline integrators provided by the Dymola tool. This numerical experiment illustrated: a) that the partitioning is feasible also for comprehensive, “real-world” models, and b) that by using a coupling of clocked discretized continuous-time partitions in combination with judiciously selected solver methods considerable simulation speedups can be achieved (the speedup factor was about 2.9 for the example model).

Despite this encouraging result, it also needs to be noted that it can take substantial efforts to find a *good* partitioning and select a combination of solver methods and corresponding integration step sizes that outperform a simulation using “conventional” solvers. Nevertheless, particularly for real-time simulations, investing that additional effort may be worthwhile if real-time constraints cannot be satisfied by using a conventional global solver approach.

## Acknowledgements

Partial financial support of DLR by the German BMBF (within the ITEA2 project MODRIO) and of Dassault Systèmes by the European Union (within the CleanSky project MODELSSA) for this development is highly appreciated.

## Abstract

Modern advanced driver assistance systems (ADAS) provide a significant increase in comfort and safety. In many cases, a single vehicle, today, contains more than one assistance system, while the trend to use ADAS continues to grow. At the same time, the number of systems that perform control interventions with safety-relevant functions increases as well. From an overall perspective, it must be assured that the driver assistance systems – individually as well as in the way they interact – function flawlessly in any driving situation and with any driver at the wheel anywhere in the world. This results in an increased development and testing effort for modern ADAS in general. In-development testing based on virtual test driving offers an approach to a solution that allows the validation effort to be significantly reduced while meeting the requirements for safety-relevant functions in the vehicle associated with ISO 26262. This is particularly evident when developing and testing new light functions, which in real-world road tests can often be performed only in conditions of darkness. Dynamic Light Functions are defined as the situation-dependent headlight adjustment consisting of cornering light, headlight leveling and (glare-free) headlight assistance. This paper presents this new methodology.

*Keywords:* FMI; AUTOSAR; CarMaker; Sil; Xil; Dynamic Light Function

## 1 Motivation and Current State of Technology

Today, new light functions are developed in the early stage based on models. These models are subsequently tested for functional performance in the Model-in-the-Loop (MiL) process using simple test cases. Based on requirement specifications, the Simulink models are subsequently migrated to C Code and put into an electronic control unit as an AUTOSAR software component (AUTOSAR-SWC). The approval occurs strictly in the Hardware-in-the-Loop (HiL) test based on real-world measurement data or stimuli. After approval of the software on the HiL-/(SiL-) test rig, testing in the vehicle commences. When using this procedure, though, feedback in the whole vehicle takes place only at a very late point in time. Today, in the Dynamic Light Functions project, dynamic SiL tests are performed based on recorded test drives and manually generated scenarios. Improvement potential still exists here with respect to certain aspects:

1. The open-loop tests, in the case of modified controller software, are reusable only to a limited extent.
2. The transfer to different vehicle configurations or new vehicle variants is possible only to a limited extent. The low availability of prototype vehicles in the various development stages does not permit any tests to be run on the physical prototype.
3. The additional evaluation scenarios which may emerge in the analysis of the interaction of the controller and controller distance have to be recorded in the vehicle test again. The

reproducibility of the scene and the large number of real-world variants is often unfeasible.

By using a vehicle model and corresponding test automation real-world effects can be examined early in the SiL approach. This SiL approach can be integrated into the seamless X-in-the-Loop (XiL) development method [1]. The limited availability of the HiL test rig resource (and the associated late availability of the whole vehicle) could thus at least be partially alleviated.

## 2 FMI Brings Light into Darkness

The Functional Mock-up Interface (FMI) [2] offers the possibility to make use of C Code and Simulink models in a standardized form as so-called Functional Mock-Up Units (FMU) in integration tools. These FMUs can be used for interaction chain tests and design decisions at a very early stage of development. In addition, they are available in the validation chain for dynamic residual bus simulation models. Furthermore, the fast and easy connection of an electronic control unit or an array of ECUs is possible as well.

An FMU can be generated quickly and at low cost using simple means. FMUs consist of a ModelDescription, i.e. a description of the interface (signals and parameters) and a container with a dynamic library for the relevant operating system. Therefore, the generation of such an FMU requires some type of interface specification (e.g. the arxml format [3]) and the associated source code and/or a previously compiled library for the relevant target systems (Figure 1). Even though some tools already offer the possibility to generate FMUs, the objective here is to point out a license-free alternative for quick implementation that can also be used to carry out new requirements with ease.

Figure 1: FMU generation.

The ModelDescription is an XML format specified in the FMI standard. All the information required to generate it is available in the AUTOSAR

specification in the form of an arxml description and is therefore retrievable in an automated form. In addition to the interface description, the AUTOSAR XML specification contains the function calls for initialization and the individual calculation steps as well as their step widths. Furthermore, the interface description provides information about the names of the buffers (global variables) for inputs and outputs as well as coding parameters. The FMU interface merely provides an array with all model variables. Consequently, they have to be additionally mapped to the global variables in order to enable the controller to process the current data.

To simplify the integration of the controller into different development environments, a floating-point to fixed-point conversion was directly implemented in the wrapper, again automatically generated from the existing signal description.

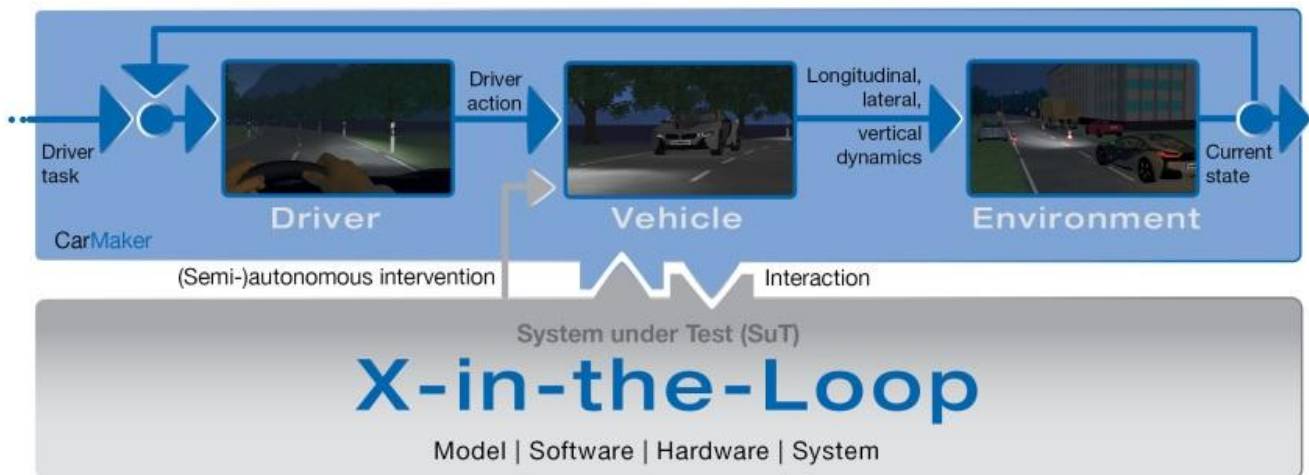

By using this information it is now possible to generate code which initially sets the parameters of the FMU and in the subsequent calculation steps manages the inputs and outputs and calls the actual controller. Together with the controller source code it is possible to compile dynamic libraries which together with the ModelDescription yield a functional FMU.

The FMUs generated in this way can be imported, linked and simulated in various integration tools.

## 3 Consistent Tests through Efficient Integration of Standardized Components

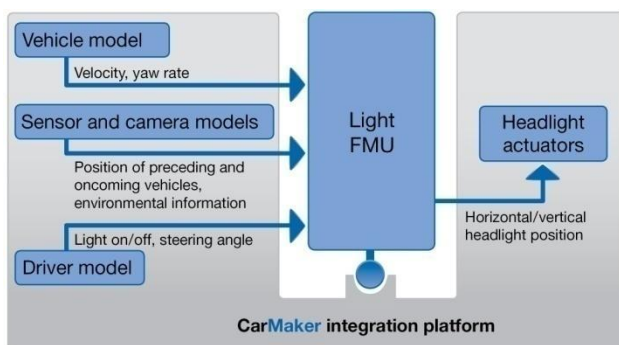

To create the link between the FMUs and the whole vehicle, additional plausible models of vehicle physics and the vehicle environment are necessary. For this purpose, the seamless X-in-the-Loop (XiL) approach was rigorously implemented in CarMaker (Figure 2).

The XiL integration makes it possible to integrate and comprehensively validate all relevant system components, either as models, ECU software or hardware, into the whole virtual and real-world vehicle. As an open integration platform, CarMaker offers interface architecture that is adapted to the vehicle development and in which the FMU approach can be efficiently used. Models, software components and real-world vehicle components are integrated by mouse click into so-called digital prototypes – from the single component through to interlinked (networked) systems.

**Figure 2:** X-in-the-Loop enables the early verification and validation of systems. CarMaker offers the appropriate interfaces to integrate all relevant components and systems into a whole virtual vehicle.

Various components such as the powertrain, assistance and control systems etc. as well as instrument and operating concepts may be integrated as needed [4]. The virtual integration creates the prerequisites to check what effects the tested components have on the overall performance of the whole vehicle. Unfavorable design decisions and even functional faults can thus be detected earlier and allow corresponding design decisions to be optimized [5]. The digital prototypes are verified as a total system in virtual test driving and serve as input for our light assistance FMU (Figure 3).

**Figure 3:** Interfacevariables to implement the light FMU into the CarMaker integration platform.

In practical terms, we receive signals from vehicle dynamics, additional environment sensors and camera systems as well as driver inputs such as steering angle or manual headlight requests. In addition to the powerful vehicle and driver model, CarMaker encompasses a complete environment simulation, consisting of roads with corresponding static traffic objects and moving traffic as well as environment sensors and digital maps (such as NAVTEQ or Google Earth). As a result, the test environment is modeled at a high level of realism, see Figure 4.

**Figure 4:** Function models and software components can be integrated into the integration environment either as Functional Mock-Up Units or hardware components. In addition, CarMaker allows navigation systems and software development tools to be connected as well.

Furthermore, as a test platform, CarMaker offers a maneuver description that is based on the principles of real-world road tests. Complex open- and closed-loop tests are carried out as maneuver instructions. The virtual test drive is reproducible and can be easily modified as needed. This makes it possible to evaluate new developments in virtual test driving and to tangibly experience them in realistic driving situations. The test cases for the light functions are migrated from test driving into the CarMaker language and carried out in the TestManager (Figure 5).

The screenshot shows the 'Test Manager' window in CarMaker. It displays a tree view of test cases under 'Global Settings'. The 'Driving\_Ser' section includes 'Variation 1' through 'Variation 4'. The 'Steer\_Ser' section includes 'Variation 1' through 'Variation 3'. The 'Backwards\_Ser' section includes 'Variation 1' through 'Variation 3'. Each variation has associated parameters like Velocity and Steeringangle, and a 'Res.Date' column showing test results.

Item Description	Par1	Par2	Par3	Par4	Criteria	Res.Date	Result
Global Settings							
Driving_Ser

**Figure 5:** Test cases from real test driving.

By combining in-development testing, the standardized FMI and the multi-domain integration and test platform the development and test effort can be significantly reduced. A maneuver catalog that has been defined once is thus available for design, verification and validation purposes in all stages of the development process. The maneuver catalog is specifically extended according to the development stage in order to comprehensively verify and validate the design and implementation of the ECU software. This allows fast, convenient exchanges and testing of vehicle components as FMUs, both within the BMW organization and in collaboration with suppliers. In other words, the OEM and the suppliers are able to use the same models and functions for architectural decisions and virtual test driving.

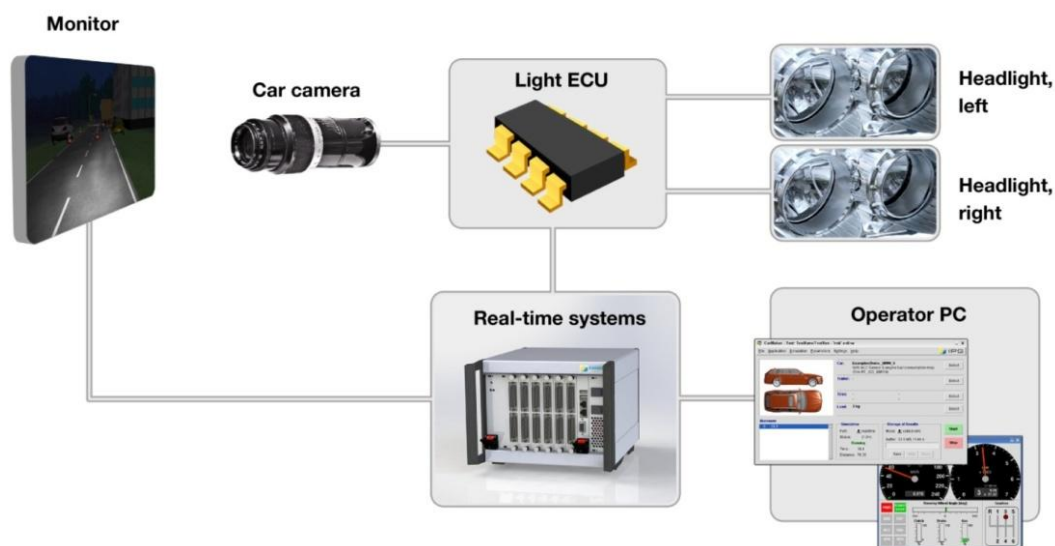

## 4 Use in the Development Process

Last but not least, this is where the advantages of virtual test driving prove their viability (Figure 5): providing test scenarios (through to complex customer use cases) which can be modified as needed and are reproducible on the one hand and reproducible test results on the other.

In the development process, FMUs can be used in an SiL environment at an early development stage. Software modifications and their effects on existing test cases can be easily realized and tested due to the standardized components.

Aside from this range of applications, FMUs can also be used as substitutes for electronic control units not currently in existence in an array or composite of ECUs together with existing, real-world ECUs. This way, they help to make tests on the whole system possible at an early development stage.

In the case of the dynamic light function, in addition to numerous vehicle dynamics parameters provided by CarMaker, camera-based information is processed as well. This information is either provided by virtual sensors or – ideally – by the real ECU of the camera. To enable the ECU to actually deliver realistic values, virtual driving scenes including other traffic from CarMaker are captured and processed by the camera in a darkened room. This means that the virtual test drive is filmed by the real-world vehicle camera in order to run a so-called interaction chain test. The camera is used to detect the presence of other vehicles within the blinding range of the light. This information is forwarded to the light function in order to activate the glare-free range of the high beam (Figure 6).

**Figure 6:** Set-up of an HiL test rig for the event chain test: Operator PC and HiL system, real-world or simulated controls for the light, light ECU, headlights with headlight actuators, camera with integrated ECU and monitor for filming.

This adds significant value compared to the tests that have been run up to now, in which only the ECU could be served with a residual bus simulation but the specific signals and functions of the camera could not be used.

Linking real-world headlights with the environment described above now represents the next step. This allows the entire interaction chain, from the camera through to the actuator, to be modeled and tested. As a result, detailed statements about the functional performance of the whole system can already be made on the test rig, which makes it possible to considerably reduce the validation effort on the real-world vehicle. Figure 7 shows a snapshot from a video [6] for comparison of a real-world and a corresponding virtual test driving situation.

**Figure 7:** Comparison of the light function: video with glare-free high beam and its simulation.

## 5 Conclusions

By using both the standardized interface specification FMI and an integration and test platform (from MiL, to SiL and through to HiL) the current development process can be made significantly more efficient and the existing gap in the area of the SiL tests can be closed. In such a development environment the presented control loop consisting of the “the car on the road” and “light events detected by the camera” can be studied in detail. The control loop of interest can then be extended step by step, e.g. additionally including the position of the headlight actuators, and/or the simulated illumination of the headlights. A reduction of the testing effort associated with the large number

of variants can be achieved by the DoE (Design of Experiment) method in combination with carefully selected real-world road tests [7]. For this purpose, critical corner case parameters can simultaneously be tested in the design space to be validated and, in parallel, simulated in virtual test driving. The models on which these tests are based are validated. Proceeding from this database, additional real-world road tests could be made superfluous by the continuing validation being supported by the results thus obtained. This harbors further remarkable potential for reducing the validation effort and, ultimately, controlling this effort as well.

## Abstract

Due to the higher complexity of electrified vehicles the requirements for vehicle components and vehicle design augment and new development tools are desirable. The following paper describes the design of a hardware-in-the-loop test bench along with its structure using Modelica and a Remote Process Communication library. The aim is to support the development of components and operational strategies under realistic boundary conditions illustrated by the example of a waste heat recovery system. The test bench is planned and built up within the scope of the public founded project qOpt at the Institute for Automotive Engineering (RWTH Aachen University) in cooperation with the Forschungsgesellschaft Kraftfahrwesen mbH Aachen and the Institute of Automatic Control (RWTH Aachen University).

*Keywords: hardware-in-the-loop simulation, thermal management; vehicle simulation; combined heat and power generation, waste heat recovery, electric vehicle, Plug-in hybrid vehicle, thermal storage*

## 1 Introduction

A pursued objective of politics and industry is to improve the efficiency and reduce the emission of individual mobility. For achieving that, the electrification of the drive train seems to be a promising approach. The wide distribution of purely electric vehicles lacks due to their short driving ranges since the specific energy content of current traction battery systems is rather low which leads to a high vehicle

weight. Besides, the costs for such systems are still quite high. Plug-in hybrid electric vehicles (PHEV) or range extended electric vehicle (REEV) provide the opportunity to combine the advantages of a conventionally propelled vehicle such as their high driving ranges with the possibility of driving electrically and thus without emissions. To increase the electric driving range an efficient treatment of the electric energy is obligatory. This includes the optimization of the drive train, the reduction of the electric energy demand for auxiliary consumers for example by means of an intelligent thermal management. In order to exploit the maximum potential of such a drive train a complex operational strategy in consideration of all energy forms has to be provided. For example in the scope of the public founded project qOpt, which enables this research, especially the reduction of auxiliary electric heaters during the winter term is focused. Therefore a waste heat recovery system in form of a latent heat storage in combination with an operational strategy will be developed.

For an a priori design the requirements for new simulation tools augment. But often not every component may be simulated properly so hardware tests are still necessary. A combination of simulation models and specific hardware components in a hardware-in-the-loop (HIL) environment provides the possibility to reduce building up physical prototypes for a high number of variations.

HIL systems are widely used for control systems, like engine control units. An extension of such systems for prototyping components is the logical consequence and is to be considered further on in this paper.

## 2 Hardware-in-the-Loop System

In general, HIL simulation systems provide the opportunity for the following three points:

- Component tests and component design
- Design, test and validation of operational strategies
- Control of test bench components

Such a system is built up at the Institute for Automotive Engineering (ika), RWTH Aachen University, in cooperation with the Forschungsgesellschaft Kraftfahrwesen mbH Aachen (fka).

The main system consists of the simulation environment, the test bench components and its controls and the data exchange process. All three systems are explained further in the following sub chapters.

### 2.1 Holistic Model Library

For the mentioned reasons a holistic model library has been developed at the ika in cooperation with the fka and is constantly increased and improved [1].

The library contains different kinds of vehicle models, including their drive train, passenger cabin, and their respective cooling circuits. Also building systems may be considered, to solve future problem issues like vehicle-to-home (V2H) or vehicle-to-grid (V2G) applications. All models can be controlled and evaluated under different dynamic boundary conditions (e.g. drive cycles, ambient conditions) (cf. Fig. 1).

Fig. 1: Holistic simulation approach

The library is implemented following an approach of high scalability and modularity, so the level of detail may be adjusted depending on the issue to be investigated (cf. [1]).

### 2.2 Thermo-hydraulic test bench

The common interfaces for thermo-hydraulic simulations are the temperature, volume flow rate and the pressure. When emulating physical systems in a simulation environment the respective physical values have to be provided with a thermo-hydraulic test bench at every time step. The used test bench for the HIL system is shown in Fig. 2. For the hydraulic part, a controllable fluid pump and several controllable valves are integrated to adjust the volume flow rate and the relative pressure at the device under test (DUT).

The temperature is regulated with a heating device and a fluid cooling system. When connecting a refrigerant system also temperatures less than ambient temperature can be achieved.

The test bench is operated by a CompactRIO system. Since the system is not hardly real time capable with bigger models also a PXI System may be connected, which is presented in [3].

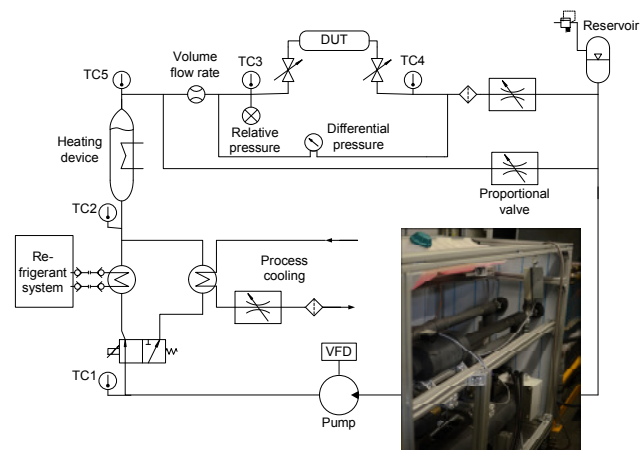

Fig. 2: Thermo-hydraulic test bench

### 2.3 Data Exchange Process

The software configuration of the HIL consists of several applications, which are simultaneously working together. The participating applications address different concerns at the HIL, e.g. simulation and test bench control.

Proper execution and interaction of all applications need to be assured. Thereby the resulting challenge for the HIL system is the elimination of unwanted side effects between the applications in order to avoid mutual interference of the applications during operation.

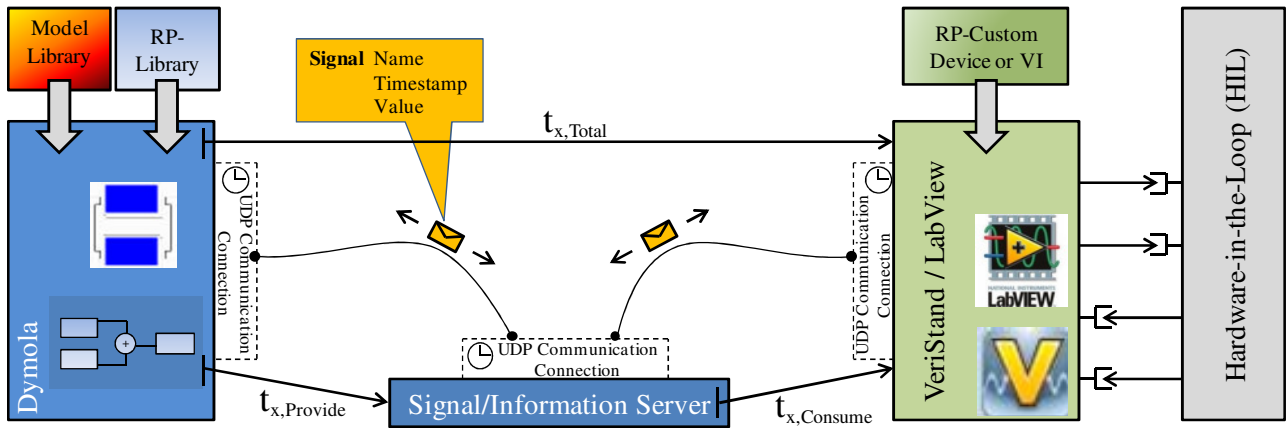

Fig. 3: Software structure of the HIL system. Multiple applications are joined for operation.

An overview of the participated applications currently in use at the HIL is shown in Fig. 3. Most important are Dymola and LabVIEW. Dymola is responsible for hosting the physical model of the surrounding environment, which generates control requests for the test bench and the DUT. The management of the HIL system itself is based on National Instruments LabVIEW [6] in optional combination with VeriStand [7], executed on a CompactRIO hardware and a Windows based personal computer. The CompactRIO executes all requests coming from the physical model output. LabVIEW in combination with the CompactRIO ensures reliable control of the hardware of the test bench and keeps the test bench within applicable operating conditions.

At the same time LabVIEW and the CompactRIO capture measurement data from test bench and DUT and return these back to the physical simulation in the Dymola environment. As Dymola is normally not targeted for real-time interaction with control components, new coupling features have been integrated to Dymola in order to implement the previously mentioned linkage of applications.

The connection between the applications is realized by an additional Remote Process Communication (RPCom) interface library, developed at fka. The library provides communication and synchronization elements, which are added to the physical model in Dymola in order to build an externally accessible interface with input and output data (cf. Fig. 4). This interface is accessible while the simulation is running. Corresponding elements of the RPCom Library are as well integrated in a LabVIEW VI<sup>1</sup> or in VeriStand using a RPCom Custom Device [8].

<sup>1</sup> Individual, decoupled operation of all applications can be performed even if the RPCom elements have been integrated, allowing enhancements of the physical model and the test bench in parallel without removing the RPCom elements.

The RPCom library is implemented in .NET and embedded by Dymola using a system native c wrapper [5]. To allow access to the .NET components by the system native functions called by Dymola the intermediate code is modified such that all managed code elements are exported with system native interfaces [9]. The RPCom functionality can be used to even extend the co-operation of tools at the HIL to further applications, like e.g. a driving simulator, if these are required.

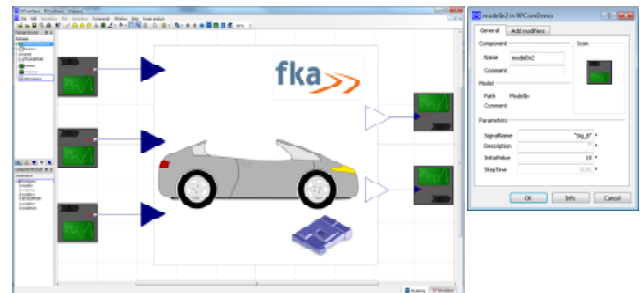

Fig. 4: Simple physical model in Dymola with additional RPCom elements

Main responsibility of the RPCom library is binding the individual applications together by organizing a coordinated signal exchange. This is realized by the RPCom library using UDP communication making distributed execution of all applications on a multi-computer network possible, completely decoupling the control of the test bench hardware from the simulation itself. Supplementary to data exchange, a synchronization functionality for all applications, necessary to make the operations of simulation and test bench behaviors coherent, is taken out by the RPCom library.

The exchange of signals between the applications is organized by symbolic IDs. Finally this means that all signals are managed within a signal pool by an unique symbolic name, which is associated with in-

formation on the corresponding value among with a the timestamp of last known validity of the value and supplementary meta-data, like physical unit or a detailed signal description. Currently, all elementary data types, such as double, integer or boolean values are supported. Vectors shall be supported in a future extension of RCom.

All signals are initially stored in local caches assigned to each participating application. In regular, configurable cycles - which depend on the timing requirements - these caches are synchronized. The synchronization can be selected to match the individual timing requirements of the application, avoiding unnecessary data exchanges. Altogether the synchronized signal caches of the applications build up a distributed information server.

For reliable HIL operation, the connection of applications and the timing behavior realizable by the RCom library are relevant in order to ensure deterministic HIL operations.

Fig. 5: Signal travel time ( $t_{x,Total}$ ) and distribution measured during HIL operation for exchanged data between the coupled applications. Configured cycle time is 10 ms.

Due to the systems thermal inertia, soft hardware requirements can be applied for the cooperation.

Fig. 5 shows a timing measurement executed on the HIL system with a configured synchronization time of the application caches of 10 ms by the RCom library. In the analyzed scenario Dymola and LabView are operated on the same machine. A pool of 25 signals is exchanged between the applications. The cycle time of the Dymola Model is 100 ms while HIL cycle time for test bench control is set to 10 ms. As the measurements in Fig. 5 implies, the exchange rate is very stable around 10 to 20 ms.

The benefit of the integration of the RCom library is to distribute different HIL concerns to multiple computer systems within a network, e.g. decoupling hard real-time from weak real-time requirements. Also an easy partitioning of different Dymola model segments to more than one computer system can be realized, allowing integration of even complex and computation time intensive model configurations. Both benefits are utilized within the HIL system.

### 3 Augmented CHP usage of the internal combustion engine in electrified vehicles

Especially in winter terms the thermal management of electrified vehicles represents a major challenge. A temperature sensible component e.g. the traction battery needs to be conditioned and heating energy has to be provided for the passenger cabin. When driving purely electrically the heating energy has to be supported electrically which directly affects the electric driving range. Thus, waste heat recovery is a promising approach.

In the scope of the project qOpt the electrified vehicle Opel Corsa Hybrid 3 (cf. [2]) of ika is converted to a Plug-in-hybrid electric vehicle. Besides, an optimization of the thermal management of the vehicle is considered. In this article the potential of the integration of a thermal storage into a PHEV to enhance the electric driving range is further analyzed by means of hardware-in-the-loop simulations.

#### 3.1 System architecture

The vehicle data including the passenger's cabin are listed in Tab. 1. Since the internal combustion engine (ICE) has a high potential for waste heat re-

covery, the ICE and its cooling circuit is considered as the device under test (DUT).

Opel Corsa Hybrid	
empty weight	1150 kg
power (ICE)	44 kW
power (electric machine)	37 kW
battery capacity	16 kWh
cabin volume	3 m <sup>3</sup>
window surface	2 m <sup>2</sup>

Tab. 1: Vehicle data of the Opel Corsa Hybrid 3

In Fig. 6 the schematic hardware setup is shown. An additional heat exchanger (HEX) is integrated into the cooling circuit of the ICE to provide the possibility to warm up the ICE or use its waste heat. The heat exchanger is the interface between both the electrified vehicle and the HIL system. Since the integrated pump is belt driven, an additional electric pump is integrated to achieve higher volume flow rates when driving at low engine speed or when driving purely electrically. Furthermore to monitor and control the cooling circuit, different sensors for volume flow rate, relative pressure and temperatures are integrated.

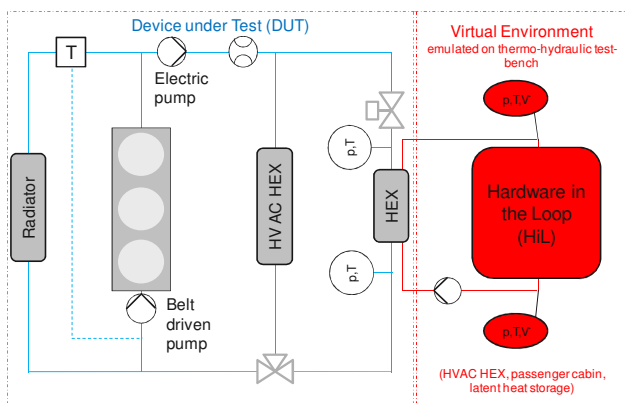

Fig. 6: Schematic view of the HIL setup and its connection to the cooling circuit of the internal combustion engine

To analyze the waste heat at different driving cycles, the vehicle is placed on a dynamic chassis dynamometer. The driving resistance for the specific Opel Corsa are adjusted, so a realistic power output is achieved. The current test setup is shown in Fig. 7. As mentioned above a winter term scenario and the possibility of waste heat recovery is analyzed. But since with this setup the winter term boundary conditions can only be adjusted to the ICE it is necessary to simulate the remaining vehicle components. For

this purpose inter alia the library mentioned in chapter 2 is used.

Fig. 7: System setup with the Opel Corsa on the dynamic chassis dynamometer connected to the HIL test bench

### 3.2 Simulation models

In the application case all thermal energy sinks are modeled in Dymola/Modelica. This includes the model of the passenger cabin and the HVAC unit. Besides, a thermal storage is considered. The heat exchanger of the HVAC uses the measured temperature to calculate the heat flow rate into the cabin. The heating demand is determined by the passenger cabin model. It includes the different convective and radiative heat flow rates to and from the environment (cf. Fig. 8 and [4]). Inside the heating circuit an additional electric heater is installed to provide heating energy when the vehicle is driven purely electrically.

Fig. 8: Energy flows in passenger's cabin model

In this application example a latent heat storage was chosen. It is modeled according to [10]. The latent material has a melting temperature of about 65°C. Depending on the temperature gradient between the cooling fluid and the latent material the thermal conductance is calculated.

### 3.3 Scenario and boundary conditions

To analyze the benefit of an advanced combined heat and power (CHP) usage of the ICE (engine data cf. Tab. 1) a realistic scenario is defined. A drive cycle with a highway part and a rural part is used for the simulations. On the highway the vehicle is propelled by the internal combustion engine at a constant speed of 110 km/h. The waste heat is used to warm up the ICE and to provide heat for the passenger's cabin. Shortly before the thermostatic valve opens (engine is warmed up) a valve is operated, opening the bypass to the thermal storage. In this way an advanced combined heat and power generation usage of the ICE is achieved since the opening time of the thermostatic valve is minimized. Thus, less heat is rejected to the environment and a higher amount of waste heat is used. As mentioned before, all heat sinks are simulated in Modelica and the respective heat flows rates are transferred from the engine's cooling circuit in the thermo-hydraulic test bench.

Subsequently, the vehicle enters a rural zone (Urban part of HYZEM cycle) and is operated purely electrically. The stored energy from the thermal storage is then used for providing heating energy for the passenger's cabin, so the high value electric energy need not to be used for heating purposes.

As ambient conditions a typical winter scenario is chosen (0°C ambient temperature, 100 W/m<sup>2</sup> solar radiation) (cf. [11]).

## 4 Results

In Fig. 9 the dynamic profile of the engine cooling temperatures before and after the heat exchanger that is connected to the HIL are shown (cf. Fig. 6).

The initial temperature of the engine is 10 °C. The waste heat of the ICE warms up the engine and by the means of the heat exchanger in the HVAC the passenger cabin. At the beginning only little heating energy is transferred through the HVAC heat exchanger because of the low temperature gradient. At a temperature of 84 °C in the ICE cooling circuit the valve, to regulate the volumetric flow through the thermal storage is opened. Due to the high temperature gradient a high amount of heat is transferred to the thermal storage. The measurement clearly shows this point. Both the temperature before and after the heat exchanger are reduced. Subsequently the temperature gradient and therefore the heat flow rate into the storage decreases (cf. Fig. 9).

Fig. 9: Engine cooling temperatures before and after heat exchanger (cf. Fig. 6)

Fig. 10 shows the dynamic curve of the heat flow rate to the cabin and to the storage. Within the first 300 seconds the heating power increases since the engine cooling temperature increases. After that the control unit for cabin heating demands a lower heating power to maintain comfort temperature (cf.[4]).

Fig. 10: Heat flow rates for the passenger's cabin heating and to the PCM storage (cf. Fig. 6)

In Fig. 11 the temperature curve of the thermal heat storage is shown. The melting point of the latent material is clearly stated out. At the end of the ride the thermal storage reaches a temperature of about 85 °C. The contented energy amounts about 700 Wh.

During the subsequent purely electric ride the heating energy may be used for cabin heating and by this the heating demand for the next 600 seconds may be provided nearly completely by the stored waste heat of the combustion engine. Thus, the electric driving range can be enhanced by about 4 km.

Fig. 11: time dependent temperature curve of the latent heat storage

## 5 Conclusion and Outlook

Due to the higher complexity of electrified vehicles the requirements for vehicle components and vehicle design augment and new development tools are desirable. In this article a HIL system using Modelica and an UDP interface has been presented which was developed at the Institute for Automotive Engineering (ika), RWTH Aachen University, in cooperation with the Forschungsgesellschaft Kraftfahrwesen mbH Aachen (fka). The connection between the applications is realized by an additional Remote Process Communication (RCom) interface library, developed at fka.

Performance tests show that the connection of applications and the timing behavior is reliable to ensure deterministic HIL operations, at least for low real time requirements. Besides, by this data exchange progress it is possible to separate the simulation and the test bench control hardware, especially when models with a higher complexity demand high performance hardware.

An application example was given in which the potential of integrating a thermal heat storage unit into the cooling circuit of the ICE of a PHEV was investigated by means of HIL simulation. In order to measure the usable amount of waste heat of the ICE the vehicle was placed on a dynamic chassis dynamometer. All heat sinks, like the passenger cabin as well as the thermal storage were simulated in Dymola and the respective physical values were transferred to the thermo-hydraulic test bench. The results show that a reasonable amount of waste heat could be recovered in a thermal storage. Therefore, the electric driving range can be enhanced by provid-

ing the heat energy of the passenger cabin by the thermal storage unit.

The HIL system will be used further in the project qOpt to develop an operational strategy in consideration of the heat demand for electrified vehicles taking into account a latent heat storage system. Besides, in another project an electrical and thermal coupling between vehicles and buildings will be investigated further on.

## 6 Acknowledgement

The authors would like to thank the State of North Rhine-Westphalia/EFRE for their financial support in the research project qOpt.

## Abstract

This paper highlights the use of a coordinated suite of Modelica libraries for vehicle thermal management applications. The models are implemented using the Vehicle Dynamics Library, Liquid Cooling Library, and Heat Exchanger Library from Modelon. An integrated vehicle thermal management model is implemented, including the key physical and controls models. The model is used to highlight complex, multi-domain interactions between the physical and control systems over drive cycles for combined thermal and fuel efficiency studies. The model is also used to support controller development and optimization as an FMU integrated into Simulink. The flexibility of FMI-based workflows is also illustrated via batch and Monte Carlo simulations in Excel. A heat exchanger application coupling inputs from CFD illustrates the use of higher fidelity models from Heat Exchanger Library for calculation of performance degradation due to non-uniformity.

*Keywords: vehicle thermal management; thermal systems; fluid systems; vehicle modeling; powertrain; engine; transmission; controls; Simulink; FMI*

## 1 Introduction

To meet increasingly stringent fuel economy and emissions standards, automotive original equipment manufacturers (OEMs) and suppliers have sought novel technologies to increase fuel efficiency. Given the complexity of vehicle systems, the need for increasingly sophisticated analytic tools to perform concept evaluation, capture multi-domain system interactions, and develop and validate control strategies grows. A Modelica-based platform for simulation of vehicle systems is ideal for this type of work as it naturally captures multi-domain interactions, allows flexibility in model complexity to support a

range of applications, and supports integration of physical and control systems.

Traditional vehicle models for fuel consumption have often ignored thermal effects as the inclusion of thermal effects increases the model development and parameterization effort and can affect computational efficiency for models which are run on drive cycles which can be thousands of seconds in duration. However, in the search for fuel efficiency gains, advanced technology is rapidly advancing from research and development to production, including the associated controls development. Due to the complex interactions between vehicle subsystems, vehicle thermal management (VTM) requires a holistic approach to minimize energy consumption without violating thermal limits for the various systems. Previous work in Modelica has highlighted this need for thermal management of electrified vehicles [1].

A real world example of a vehicle level technology that has the potential for fuel economy gains, but with a direct impact on thermal management is grill shutters. Grill shutters can be used to restrict or completely close airflow to the front of the vehicle. While this reduction in airflow positively impacts fuel efficiency by reduction in aerodynamic drag, reduced airflow through the front end of the vehicle degrades cooling capacity through the heat exchanger stack which contains the radiator, condenser, and potentially additional coolers such as oil and charge air coolers. Grill shutters can be mechanical or potentially even actively controlled. Clearly attribute balancing at the vehicle level is required to manage fuel consumption gains and the cooling requirements for the various fluid systems over a range of driving conditions and ambient environments. Active grill shutters can be found in production on a range of vehicles from various manufacturers, including the Ford Focus, Chevrolet Cruze, Cadillac ATS, Dodge Dart, and Ram 1500 [1].

To illustrate the complex interactions between vehicle subsystems, vehicle controls, and thermal

controls, an integrated vehicle thermal management model is implemented with grill shutters. The models are implemented using a coordinated suite of Modelica libraries from Modelon. The models are implemented using the Vehicle Dynamics Library (VDL) [3], Liquid Cooling Library (LCL) [4], and Heat Exchanger Library (HXL) [5]. The model captures vehicle dynamics on drive cycles including key thermal dynamics. The model also includes critical vehicle controls and thermal controls for the grill shutters and fan. This paper provides an overview of the model, key subsystem implementations, and key features of the various libraries to support this type of modeling.

The integrated vehicle thermal management model is used as a demonstrator for Modelica-based workflows for illustrative controls development and robustness applications. The controls development application illustrates the implementation and optimization of an active grill shutter strategy. The Modelica VTM model is exported as an FMU via Functional Mock-up Interface [6] for integration in Simulink with the grill shutter and fan controls. Integration in Simulink is via FMI Toolbox for MATLAB [7] from Modelon. DOE techniques are used to optimize the combined grill shutter and fan settings for minimum fuel consumption. A sample optimized controller is implemented to show the fuel economy impact on several different drive cycles. Sample robustness studies are also performed with the VTM FMU in Excel via FMI Add-in for Excel [8] from Modelon. These applications include batch simulations and Monte Carlo simulations and also illustrate some of the scripting capabilities in FMI Add-in for Excel. Workflows that involve coupling higher fidelity models from Heat Exchanger Library with CFD input data for heat exchanger performance are shown.

This paper describes a coordinated suite of libraries for vehicle thermal management, an integrated model including grill shutters, and applications of this model for controls development and robustness using FMI. These examples illustrate the multi-domain approach needed for vehicle thermal management applications. Given the importance of model deployment outside of traditional CAE environments to support model-based systems engineering, workflow aspects via FMI are highlighted.

## 2 Integrated VTM Model

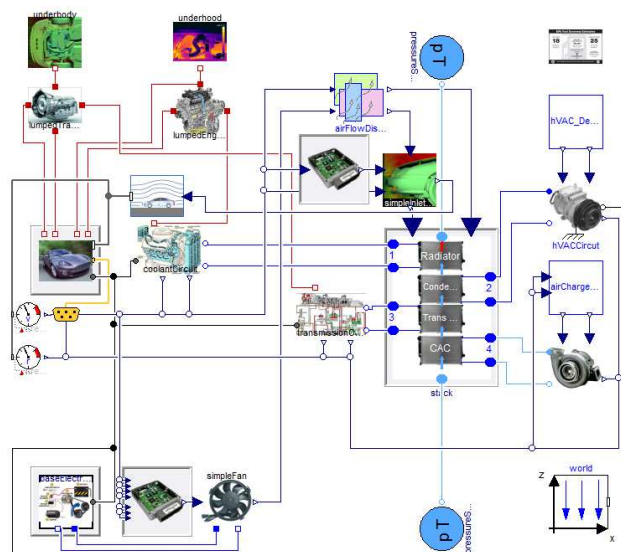

This section outlines the key multi-domain component and subsystem models in the integrated VTM model that support the subsequent applications. The

main model components and subsystems are detailed. The model shown is representative of system level models for use in thermal system design and performance characterization with parameterization as a demonstrator model and thus does not include any customer-proprietary data (future publications will highlight industrial models and applications pending publication approval). The vehicle parameterization data was taken from a sedan implemented in VDL. The majority of the thermal parameters were estimated from authors' experience with similar systems in industrial applications.

## 2.1 System Model

Figure 1 shows the integrated VTM model. This model is structured in a thermal-centric way such that the key thermal subsystems are visible at the top level of the model and in parallel with the vehicle model. At this level, the model contains the following subcomponents with key systems to be described in more detail in subsequent sections:

- Lumped 1D conventional vehicle model with automatic transmission
- Lumped thermal models for engine and transmission
- Simple underhood models for engine and transmission heat transfer
- Controllers for fan and grill shutters
- Coolant and transmission oil fluid circuits
- Heat exchanger stack with radiator, condenser, transmission oil cooler, and charge air cooler
- Minimal HVAC and charge air circuits
- Electric fan with simplified vehicle electrical system

**Figure 1. Integrated VTM model**

## 2.2 Vehicle Model

The vehicle model is implemented using the vehicle model architecture and components from Vehicle Dynamics Library [3]. This architecture supports the full range of vehicle models from lumped 1D to geometry-based full 3D representations suitable for vehicle dynamics and handling applications. Previous work [9] has illustrated drivability applications using Vehicle Dynamics Library with simplified chassis representations. A similar approach is used to create a computationally-efficient lumped 1D vehicle model suitable for drive cycle simulations. This model focuses on core loads and losses to ensure that the engine operates at the appropriate operating conditions for accurate fuel consumption and heat generation. Both the mapped engine and transmission generate heat input to the thermal system via thermal connectors added to the vehicle architecture. The simplified chassis model with rigid axle, no slip tires, and a single lumped mass is shown in Figure 3. Parameterization for the vehicle model is taken from a sedan model in VDL.

Figure 2. Vehicle model augmented with thermal behavior

Figure 3. Simplified 1D chassis model

## 2.3 Fluid Circuits

Fluid circuit modeling is a key part of the VTM model. An efficient thermo-fluid implementation is critical as it is common for a VTM model to include several different fluid circuits which interact with the thermal system and heat exchanger stack. Liquid Cooling Library [4] is ideal for modeling incompressible fluid circuits due to its efficient formulations which can support models with minimal number of pressure states, potentially even a single pressure state per circuit, while maintaining thermal states as required throughout the system. This approach eliminates the stiffness and resulting computational impact of modeling incompressible flow circuits as minimally compressible.

Figure 4 shows a simple coolant circuit implemented to support the demonstrator VTM model. This model includes the following components from Liquid Cooling Library:

- Coolant pump driven by crankshaft
- Coolant path through engine head and block
- Thermostat to control flow to radiator and via bypass
- Expansion volume

A similar model is implemented for the transmission oil circuit.

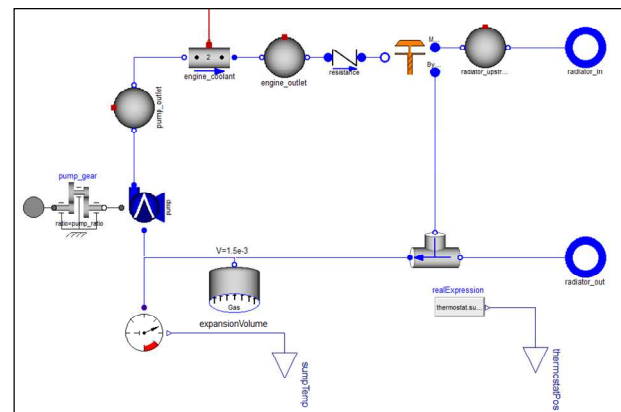

Figure 4. Simple coolant circuit

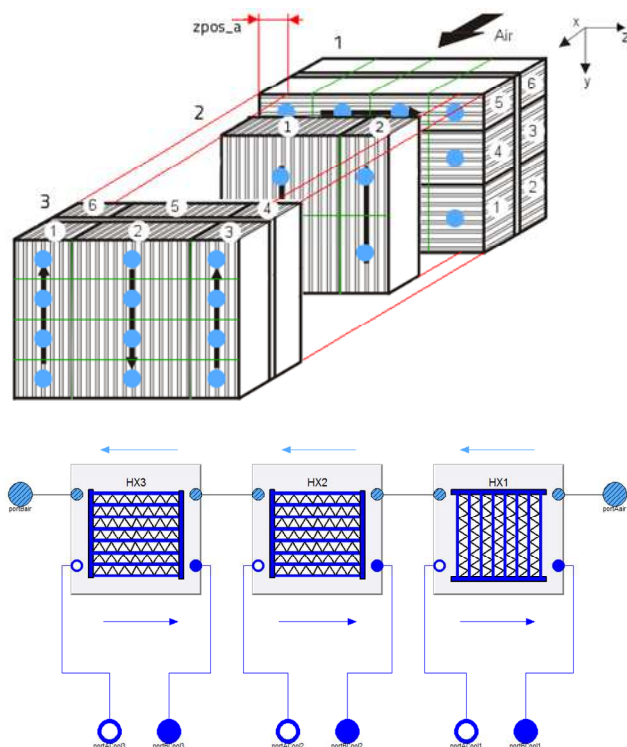

## 2.4 Heat Exchanger Stack

The heat exchanger stack is a key coupling point between the fluid circuits. Both Liquid Cooling Library and Heat Exchanger Library include models of heat exchanger stacks. These models differ in terms of model detail. Heat Exchanger Library allows detailed, geometry-based models which can be stacked using a streamtube approach for the airflow that preserves non-uniform conditions for each heat exchanger throughout the stack. The heat exchanger models in Heat Exchanger Library can be discretized

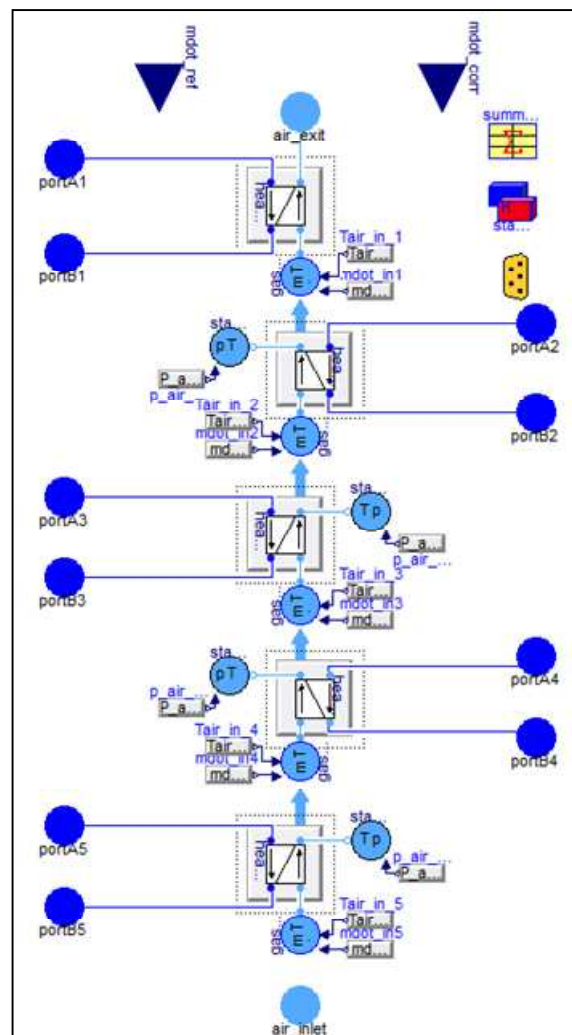

and can accept both uniform and non-uniform airflow inputs. The approach and a sample model are shown in Figure 5. This formulation is efficient enough to support drive cycle work assuming a reasonable number of stream tubes. The stack models in Liquid Cooling Library require only the basic stack geometry and can use mapped heat exchangers with imposed airflow based on external inputs from CFD, etc. The air temperatures through the stack are calculated based on the stack geometry with a single calculated input temperature for each heat exchanger based on preceding heat exchanger outlet temperatures. LCL includes assembled stack models ranging from 2-8 heat exchangers.

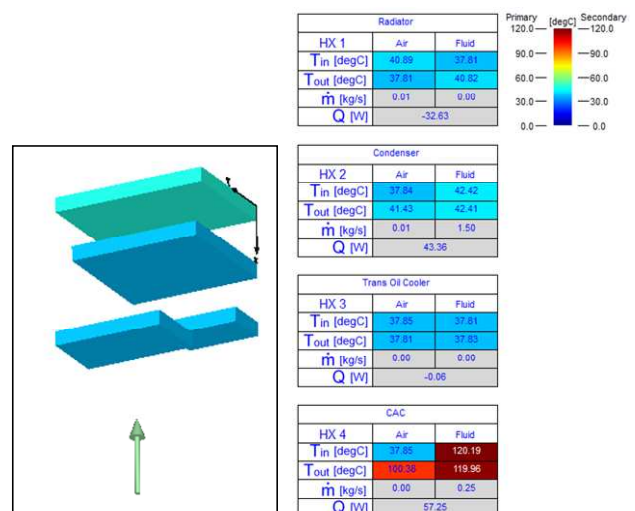

Figure 6 shows the heat exchanger stack used in the VTM model. The stack consists of a radiator, condenser, transmission oil cooler, and charge air cooler. Figure 6 shows the visualization of the stack geometry which also provides dynamic visualization of the temperatures during the run. The dynamic summary visualization for the temperatures, flowrates, and heat transfer in each heat exchanger is also shown. Each heat exchanger is implemented as a mapped effectiveness as a table of the fluid and air mass flow rates. Though simplified, effectiveness data is often available early in vehicle programs and thus can support upfront cooling pack concept assessment and early thermal system design and performance.

**Figure 5. Streamtube approach and sample stack from Heat Exchanger Library**

**Figure 6. Heat exchanger stack**

### Figure 7. Stack geometry and summary visualization

## 2.5 Controllers

For demonstration purposes, simple controllers in Modelica are implemented for the fan and grill shut-

ters. The fan controller is shown in Figure 8. The grill shutter implementation mimics a passive grill shutter system where grill shutters are closed above a parameterized vehicle speed as shown in Figure 9. More detailed controller implementations in Simulink are discussed in Section 3.2 when the VTM model is exported as an FMU and combined with the control system in Simulink.

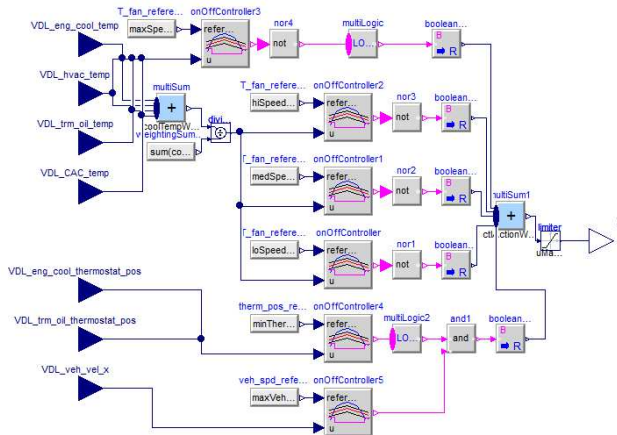

Figure 8. Simple fan controller

Figure 9. Passive grill shutter control

## 2.6 Driver and Drive Cycles

To support drive cycle simulations, the vehicle model shown in Figure 2 is augmented with a driver model as shown in Figure 10. The driver model provides closed loop trace following based on the vehicle longitudinal velocity. The driver model also handles the gear shifting for the automatic transmission based on a shift map. The driver model is adapted from the closed loop driver in VDL. Ambient and road conditions are also specified in the augmented driver.

Drive cycle selection is also implemented in conjunction with the vehicle model. Figure 11 shows the interface for drive cycle selection. Common and publicly available drive cycles are selectable from a drop down list. Custom drive cycles are supported via the “User Defined” option where the cycle data is implemented directly in the model or via the “File” option where the drive cycle data is read from a file.

## 3 Application Examples

Using the component and subsystem models outlined in the previous section, this section details several applications and workflows using the integrated VTM model.

### 3.1 Drive Cycle Simulation

The first application simply illustrates drive cycle simulations in Dymola [10] with the models described in Section 2. The integrated VTM model is simulated on the US06 drive cycle. Selected results from that simulation are shown in Figure 12. These results illustrate both the typical drive cycle simulation results along with results of a thermal system such as coolant and oil temperatures. Even with parameterization for a demonstrator model, the results are certainly reasonable and suitable to illustrate additional workflows with the VTM model.

Figure 12. Simulation results on US06 drive cycle

### 3.2 Controls Development and Optimization

While Modelica can handle both controls and physical models, a common workflow is to combine Modelica-based tools for physical modeling with Simulink for controls development. This coupling between Simulink and Modelica-based tools like Dymola is especially streamlined with Functional Mock-up Interface (FMI) [6]. While Simulink is not

natively FMI-compliant, Modelon provides the FMI Toolbox for MATLAB [7] that enables both import of FMUs into Simulink and export of FMUs from Simulink. This bi-directional coupling is extremely powerful and useful in that it allows both controls engineers and physical system modelers to leverage best-of-breed tools to support their work with a robust and straight-forward workflow for integration in either simulation environment.

For integration with controls in Simulink, the integrated VTM model in Figure 1 is simply modified to accept external inputs for the fan and grill commands as shown in Figure 13 to provide a partitioning between the physical and control systems. A model exchange FMU is created in Dymola from this model. This FMU for the VTM model is then imported into Simulink using FMI Toolbox for MATLAB and integrated with the fan and grill controllers implemented natively in Simulink. The resulting integrated model in Simulink is shown in Figure 14.

Figure 13. VTM model with external control for FMU generation

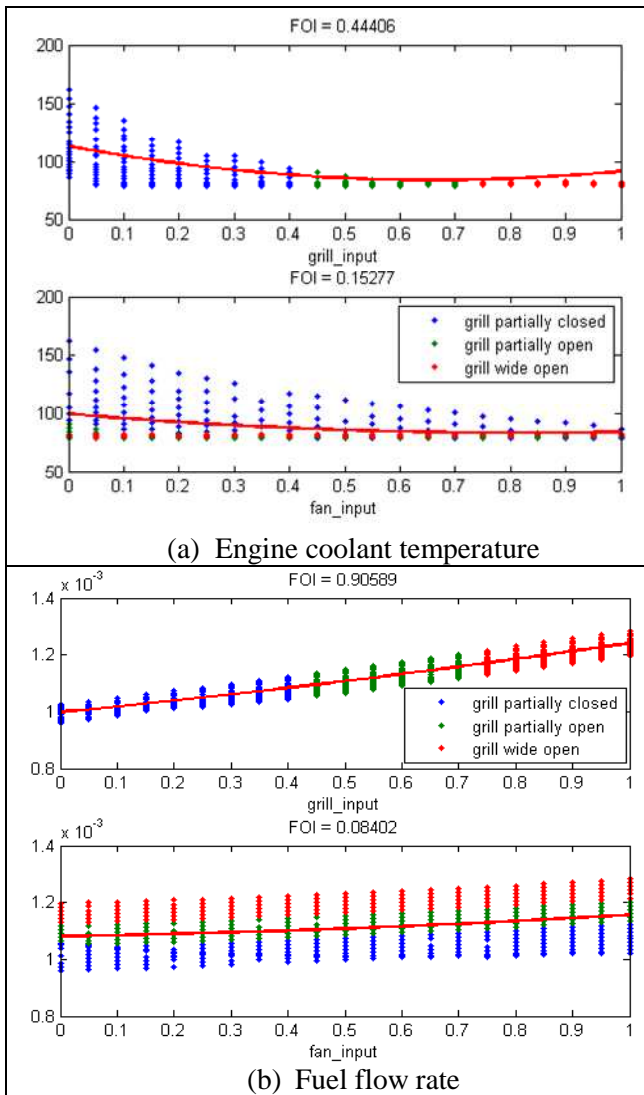

Figure 14. Integrated model in Simulink via FMU import with FMI Toolbox for MATLAB

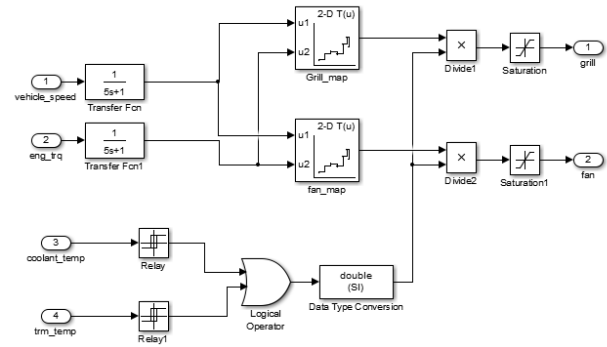

An active shutter control strategy was developed in Simulink to explore opportunities for improved vehicle fuel consumption. To help determine optimal settings for grill command and fan command, the DOE capabilities of FMI Toolbox for MATLAB to execute the runs and post-process results were used to run a full factorial sweep for grill and fan command at different vehicle speeds. Sample results for a vehicle speed of 120kph are shown in Figure 15. These DOE results can be used to identify optimal grill and fan commands that maintain desired coolant temperatures at minimum fuel consumption.

**Figure 15. Results from DOE for grill and fan commands at 120kph vehicle speed**

Using the DOE results, an active control strategy is implemented in Simulink. The implementation is shown in Figure 16. This strategy attempts to keep the grill closed as much as possible to reduce aerodynamic drag while maintaining target coolant and oil temperatures. The controller attempts to use op-

timal grill and fan settings when operating in cooling mode.

**Figure 16. Active grill shutter controller**

The active and passive strategies were run on a number of common drive cycles. Figure 17 shows the vehicle speed for the FTP MOD drive cycle. Figure 18 shows comparisons between the active and passive grill shutters for the FTP MOD drive cycle. For this drive cycle, the vehicle speeds are less than 15 m/s for the majority of the cycle. The coolant temperatures between the mechanical and active shutter controllers are compared in Figure 18. The active shutter controller can be observed to speed the warm up of the coolant temperatures by at least 2 minutes in addition to maintaining the coolant temperatures close to the desired operating point of 90°C throughout the entire drive cycle. The grill and fan commands in the mechanical shutter controller switch between off and completely on whereas the active shutter controller makes optimal use of the cooling mechanism to both speed up the warming process and at the same time maintaining temperatures close to the desired operating point. When compared at equivalent coolant temperatures, the optimal controller is expected to have slightly better fuel consumption (typical benefits of grill shutters are in the range of 0.5-2% depending on the vehicle and cycle). Of course, these results are highly dependent on the power consumption of the fan and the tradeoff between fan power and recovered aero drag and highlight the need for an analytic model to comprehend these complex tradeoffs.

**Figure 17. Vehicle speed for the FTP MOD drive cycle**

Figure 18. Comparisons between active and passive grill shutters on FTP MOD cycle

### 3.3 Batch Simulations and Robustness

The integrated VTM model can be simulated from Excel using FMI Add-in for Excel to support batch

simulations and robustness applications. To support this workflow, a co-simulation FMU is created and then imported into FMI Add-in for Excel. Experiment sheets allow users to change parameters, provide external inputs, apply boundary conditions, simulate the model, and post-process the results. The simulations are automatically run in parallel distributed across the local CPU cores. The use of FMI for model deployment outside of the model development environment is providing additional value from a standards-based workflow.

A sample experiment sheet for the VTM model is shown in Figure 19 to run the model over various drive cycles. Coolant temperature results from a batch simulation at a range of vehicle speeds are shown in Figure 20. Using the scripting API provided with FMI Add-in for Excel, Monte Carlo simulations for robustness applications are enabled. Figure 21 shows the Monte Carlo experiment sheet created by the script and results from simulations over a distribution of heat exchanger effectiveness multipliers and airflow distribution multipliers.

### 3.4 Heat Exchanger Non-Uniformity

Heat exchanger performance is a critical factor in VTM applications. While convenient to simulate with uniform velocity and temperature inputs, actual conditions typically include non-uniformity. Thus, assessing heat exchanger performance under non-uniform conditions is critical. Heat Exchanger Library [5] provides both uniform and non-uniform input sources. Figure 22 shows a test model that can be configured for either uniform or non-uniform inputs. Non-uniform inputs would typically be provided from a CFD tool and thus represent a 1D-3D coupling between CFD and the discretized 1D approach in the models in Heat Exchanger Library. Similar coupling with the Air Conditioning Library [12] for evaluating idle air recirculation has been published [13].

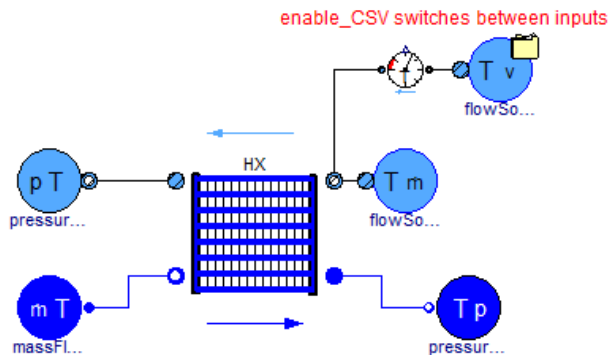

Figure 22. Heat exchanger test with option for uniform or non-uniform inputs

To verify the model, published distributions [11] were simulated and compared with analytic results from the publication for heat exchanger non-uniformity, defined as the ratio of heat transfer for non-uniform inputs to heat transfer with averaged uniform inputs from the non-uniform distribution:

$$\text{NonUniformityFactor} = \frac{Q_{\text{non-uniform}}}{Q_{\text{uniform avg}}} \quad (1)$$

The study was performed with a model from Heat Exchanger Library calibrated to bench data. The

model was then run over the published distributions in [11] for a range of heat capacity ratios with the external air as the minimum heat capacity fluid and non-uniformity results compared with published values. Figure 23 shows a sample distribution. The comparisons between the HXL simulation and the published results are shown in Table 1. Note that the results from the paper were extracted from graphs in [11]. The simulations in [11] were also run over a large range of NTU values (0-100) and it was difficult to extract values at the NTU for this cooler (roughly 1-2). Thus, the values for NTU=5 and NTU approaching zero were extracted for comparison with the model and shown in the table. The model accurately captures both the trend and magnitude of the non-uniformity.

Figure 23. Velocity distributions from patterns in [11]

## 4 Conclusions

A coordinated suite of Modelica libraries for vehicle thermal management applications have been used in the implementation of an integrated VTM model with combined vehicle fuel and thermal effects, including the key physical and control models. The demonstrator VTM model is implemented using the Vehicle Dynamics Library, Liquid Cooling Library, and Heat Exchanger Library from Modelon. Several application examples focused on vehicle thermal management have been detailed. These application examples include drive cycle simulations, controller development and optimization, batch simulations and robustness applications, and 1D-3D coupling for heat exchanger performance. These application examples demonstrate the use of sophisticated model libraries to enable the multi-domain approach needed for vehicle thermal management applications. The application examples also illustrate the use of FMI to couple the VTM model with controls in Simulink and for use in robustness application in Excel. Given the importance of model deployment outside of traditional CAE environments to support model-based systems engineering, workflow aspects via FMI are highlighted.

## Abstract

Dongfeng Commercial Vehicles (DFCV) is developing powertrain controls for a hybrid light truck. To support this development, a virtual integration platform is being implemented, using Modelica models and Functional Mock-up Units (FMUs) for the engine/EMS, gearbox, MCU/e-motors, driveline, tyres and longitudinal dynamics. Simulink models and/or c-code of the Hybrid Control Unit (HCU) and Transmission Control Unit (TCU) are also integrated in the platform to achieve closed-loop simulation. The virtual integration allows reproducing accurately the overall vehicle behavior and is used for optimization of gearshifts, hybrid mode switches and hybrid drive strategies.

**Keywords:** Hybrid powertrain, FMI, Control software

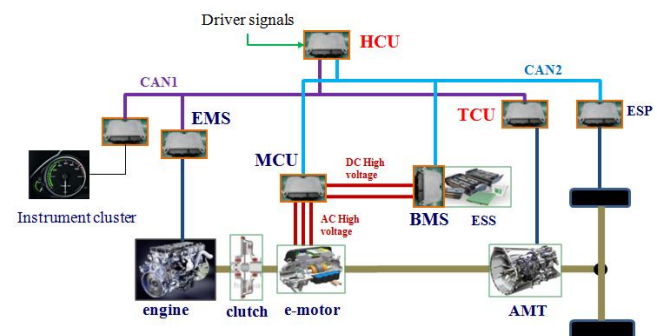

## 1 Motivation and objectives

The control systems of hybrid powertrain are generally implemented using several ECUs networked together. Functions are distributed through the controllers. Typically, the powertrain controllers will include a Hybrid Control Unit (HCU), an Engine Management System (EMS), a Transmission Control Unit (TCU), a Motor Control Unit (MCU), and a Battery Management System (BMS). Other controllers from chassis systems (ESP/ABS) might also interact with the powertrain.

The development of such a system requires considering the interactions of all main components together, namely engine, gearbox, actuation system, e-motors,

battery, driveline, tyres. For the control software, it also implies that functions cannot be developed independently but are now inter-dependent and distributed over several ECUs. This poses challenges to classical development processes.

Dongfeng Commercial Vehicles is developing such a hybrid powertrain for application in a light truck. We give a schematic of the system under consideration in Figure 1. DFCV wishes to have an efficient tool for integrating HCU and TCU control logic, optimizing parameters and performing system testing. This tool should be available for function developers, should be cost-efficient and deployable.

**Figure 1 : schematic of the hybrid powertrain**

The objective of the project described in this paper is thus to establish a *virtual hybrid powertrain* where subsystems and controllers can be simulated together on a standard PC. Function developer can then easily verify on their PC the behavior of any changes in software or parameters. This virtual powertrain can also be used for other applications, such as large coverage testing or system/parameters optimization.

For creating this *virtual hybrid powertrain*, the following tools are used:

#### **ITI SimulationX – plant models authoring**

SimulationX is a Modelica platform that provides powerful commercial libraries for powertrain modeling and electrical systems modeling [1]. The tool fully support the FMI standard and application has been demonstrated for powertrain applications [2]. Models can be exported to a standard format and can be executed without license restrictions. This is an important feature for deployment of the *virtual powertrain*.

#### **Simulink – HCU and TCU software authoring**

Dongfeng Commercial Vehicles developed HCU and TCU control software using a model-based approach in Simulink. Simulink floating-point models can be compiled and integrated in the virtual powertrain. This would be then a “model-in-the-loop” setup. It is also possible to use the final production-code (fixed point) and calibration parameters for integration inside the virtual powertrain. This method could be described then as Virtual ECUs. [3]

#### **QTronic Silver – Integration platform**

QTronic Silver is an integration platform, widely used for powertrain applications [4],[5],[6]. Silver provides the simulation core, an interactive GUI dashboard, numerous interfaces and tools for integrating plant models and control software or even performing ECU chip simulation. The Virtual ECUs described in the previous paragraph are built with the Silver Basic Software (SBS) technology.

#### **QTronic TestWeaver – Large coverage testing**

Powertrain systems, and in particular hybrid powertrain systems are systems difficult to test because of the very large number of system states and larger number of state transitions. For instance, a relevant test campaign should test all gearshifts, in various slopes. It should also test all hybrid mode transitions, under various State Of Charge (SOC). The test space is huge and test scripts/manual testing is not an efficient method. QTronic TestWeaver is an intelligent test system that can generate test cases to increase test coverage, drive the system under test to uncovered states and report problems/bugs when these are met. TestWeaver has been successfully applied in a large number of powertrain projects [5],[7],[8].

## **2 Plant models**

The plant models to be developed will be used for development support of HCU and TCU. This means that all subsystems and all remaining controllers will be modeled in the plant. This includes in particular control models for EMS, MCU and BMS.

We can define several general requirements for the plant models :

- Simulate all required bus&sensors signals (>200)
- Simulate EMS,MCU and BMS logical functions
- Simulate the necessary physics
- Simulate fast enough for convenient use
- Simulation should be accurate enough to support optimization of relevant system parameters

We describe now how plant models are developed.

### **2.1 CAN buses**

The hybrid powertrain under consideration use 2 CAN networks, CAN1 and CAN2. Dongfeng Commercial Vehicle provided the complete list of CAN messages. The 2 CAN networks are implemented as Modelica connectors.

The connectors are then used in the simulated controllers for EMS, MCU and BMS. They are also used for defining I/O variables of the FMU that will be exported from the vehicle model. The CAN1/CAN2 networks have together around 200 signals. In SimulationX, the network is considered as ideal without losses or delays besides the ECUs task cycle time. Non-ideal behavior of the CAN network is implemented and simulated in QTronic Silver which supports special features for this.

### **2.2 Automated Manual Transmission gearbox**

The AMT model consists of input and output inertias, gear stages and synchronizers. Drag torques and efficiency losses are also included. The AMT stiffness is lumped inside the synchronizers hubs.

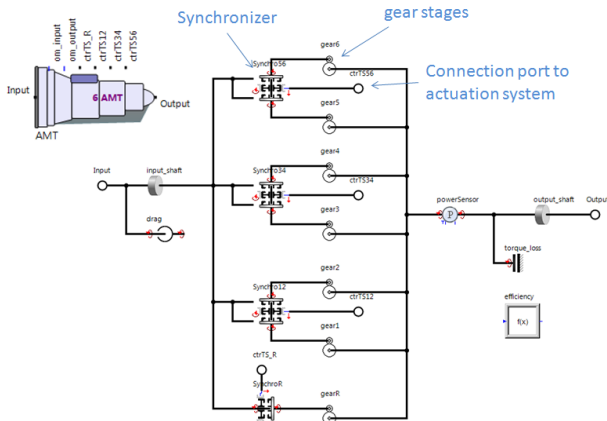

Figure 2 : AMT gearbox model

The synchronizer models are complex behavioral models that fully reproduce the synchronization process, with synchronization torque depending on actuator force. The synchronizer behavioral model has been compared to full contact-based synchronizers models in [9]. Some results of the comparisons are given in Figure 3. The detailed synchronizer model with dog-clutch gear contacts has been validated in [10].

Figure 3 : Comparison of synchronization and engagement process for detailed (red)/functional (green) synchronizer models

We can conclude that the behavioral model computes correctly the synchronization time and the engagement process. The behavioral model has the advantage of requiring few parameters and of being a “fast-running” model. It has been applied in the past in real-time simulations for HiL [9]. The synchronization time is an important quantity for the gearshifting simulation and must be simulated correctly.

### 2.3 Clutch model

The clutch model can be separated in 3 sub-components:

#### Friction/torque model:

The torque capacity of the clutch is defined as a function of the clutch actuator position. This is implemented through a look-up table. Clutch wear is

included in the modeling. Finally this torque capacity is used in a stick/slip friction model.

#### Spring force on actuator side:

The clutch actuator has to overcome the conical spring force. The spring is non-linear and has a strong hysteresis. This is implemented using a hysteresis table from SimulationX

#### Thermal model:

The clutch friction surfaces temperature is an important quantity to simulate. This is done by computing losses in the clutch during slip and using thermal capacities and heat transfer models.

### 2.4 Gearbox actuators

The gearbox actuation system is a pneumatic actuation system controlled by solenoid valves. The model is created using the SimulationX pneumatic library, where pressure/temperature are computed using mass/energy balances and compressible flow equations. The solenoid valves receive PWM signals from the TCU. The pneumatic actuation model includes all solenoid valves, gearshift cylinders and clutch cylinders. A selector gate model is also implemented. We give the overview of the pneumatic actuation model in Figure 4

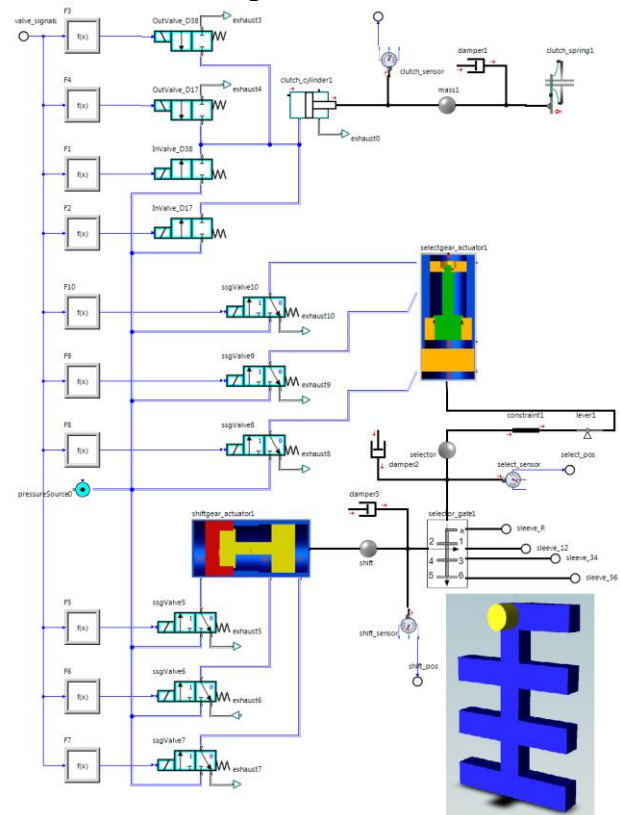

Figure 4 : Pneumatic actuation model – integrated in the vehicle model

The pneumatic actuation model can reproduce the clutch actuation dynamics. In particular, the clutch

actuation is a closed control with a position feedback. The model can be used for tuning of control gains and control laws.

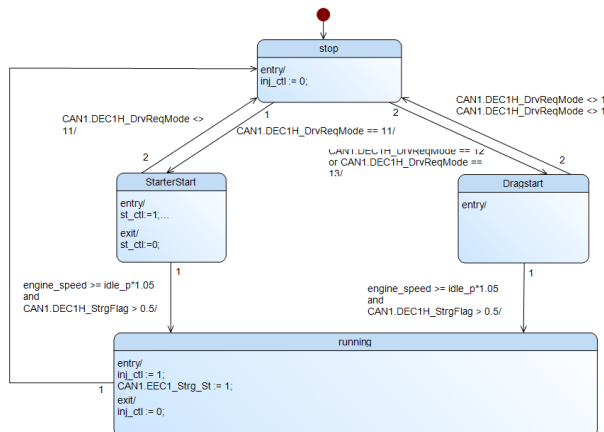

**Figure 5 : AMT with “packaged” actuation system and a soft-TCU model**

## 2.5 Engine and EMS

The engine and EMS models are based on tables defining the torque/rpm capacity of the engine, along with the fuel consumption. Turbocharger dynamics are so far neglected, but the turbocharger delay in boost pressure will probably be implemented in a model revision. Besides this rather simple table-based modeling, a state-chart is also added for simulating the logical behavior of the EMS.

**Figure 6 : Engine and EMS model**

**Figure 7 : EMS state-chart**

The EMS model must simulate the various operation mode of the engine, according to CAN requests. For instance, the EMS have a self-start mode and a “drag start” mode where the e-motor will start the engine by closing the clutch. The state-chart editor of SimulationX is thus very valuable for creating such models.

## 2.6 E-motor and MCU

The e-motor model is based on an energy/power approach. The AC 3-phase modeling is not considered and we only focus on the DC interface. The model is thus based on an efficiency approach in which the current on the DC side is computed as a function of DC voltage and motor torque. As for the EMS, a state-chart is also included in the MCU model to represent the logical behavior of the MCU software.

**Figure 8 : e-motor and MCU model**

**Figure 9 : efficiency map in the e-motor**

Motor cooling circuit is so far not modeled in detail because the focus is on HCU and TCU.

## 2.7 Battery and BMS

The battery model is based on a Open Circuit Voltage table and on parasitic and polarization resistance/capacity. The diagram of the model is shown below.

**Figure 10 : Diagram of the Battery model**

As for the EMS and MCU, the Battery Management System (BMS) uses a state-chart for handling the various states and transitions of the BMS software. The model is finally packaged as shown in Figure 11.

**Figure 11 : Packaged battery and BMS model**

## 2.8 Vehicle model overview

We give an overview of the vehicle model in Figure 12.

**Figure 12 : Diagram view of vehicle model**

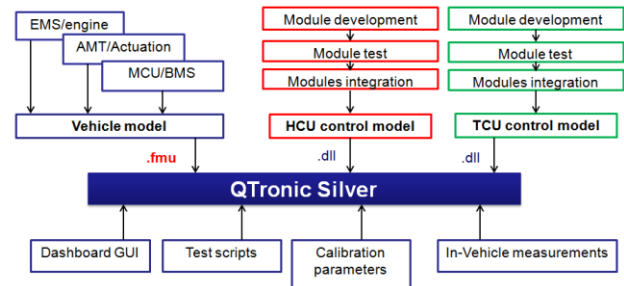

The vehicle model includes tyre with slip and driveline/propeller shaft with stiffness. The stiffness of the driveline is so far lumped and set according to an equivalent stiffness computed from CAD drawings. This assumption will probably be reviewed in future model updates.

## 2.9 Export of the model as an FMU

The plant model input/outputs are defined in the Code Export wizard of SimulationX. In particular the definition of CAN buses is helpful. The model is exported so that exported FMU variable names correspond exactly to the names defined in the CAN bus definition. This will be an important property when doing integration in Silver.

## 3 Hybrid powertrain integration

The integration flow of the HCU/TCU control software and plant is summarized in the figure below. The plant model is exported from SimulationX as a FMU, using the Functional Mock-up Interface. The control models are built using Simulink Coder and Silver Basic Software scripts.

**Figure 13 : Integration flow for plant model and controllers**

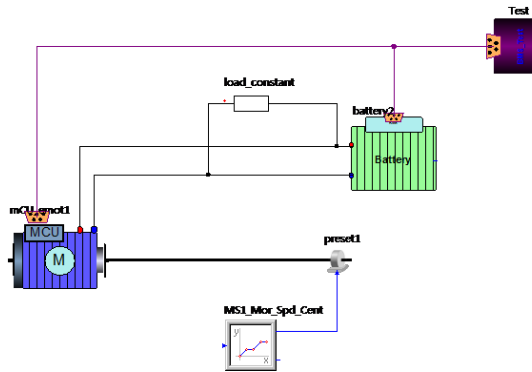

Silver-built controller models also provide access to all internal signals and all internal parameters of the Simulink models. This provides very valuable support for analysis, debugging and calibration of controllers.

## 4 Validation/calibration of models

### 4.1 BMS – MCU system validation

The High voltage circuit of BMS, MCU and DC accessories load is validated independently by using comparison between in-vehicle measurements and simulation results. The model unknown/uncertain parameters are first calibrated. These unknown parameters are typically the polarization resistance and polarization capacity and some MCU control software properties. The model used for this calibration/validation work is shown in Figure 14. Boundary conditions such as motor speed and motor torque target are imposed according to vehicle measurements. Some results are presented in Figure 15 and Figure 16.

**Figure 14: High voltage Electrical system validation model**

**Figure 15 : Battery voltage, comparison of in-vehicle measurement and simulation results**

**Figure 16 : Comparison of in-vehicle measurements and MCU/BMS currents and Battery State Of Charge**

The results for the BMS/MCU validation gives a very good agreement for the MCU current, battery SOC and battery voltage, including transients effects on the battery voltage. Difference between simulated SOC and recorded SOC is a static offset due to initial value of SOC.

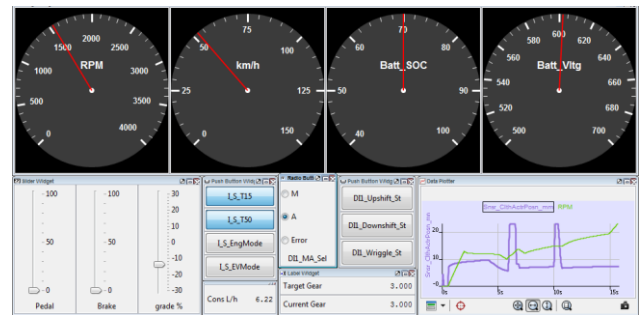

## 4.2 Complete vehicle simulation

A special attention was given first to increase simulation speed. For instance unnecessary events in the exported FMU were removed, some high frequencies dynamics were neglected because irrelevant for the

work at hand. However, since we are using variable step solvers, quantifying exactly simulation speed is not possible since it will depend on the driving case. We give however rough estimates:

- When the vehicle is idle or in steady-state without gearshifts, simulation runs 20x faster than real-time.
- When the driving sequence involves numerous gearshifts, simulation runs 3x faster than real-time.

We give in Figure 17 a partial view of the graphical controls and displays used in the QTronic Silver, where the plant model, HCU and TCU are integrated together, with around 250 signals exchanged at 10ms time cycles between controllers and plant. The complete vehicle validation is still under progress at the day of writing.

**Figure 17 : Extract of dashboard/instruments for interactive simulation in OTronic Silver**

## 5 Applications and benefits

The above virtual powertrain will be used for several applications that we list below.

## 5.1 Control software development support

The virtual powertrain in QTronic Silver has very desirable properties to support the work of function developers for the TCU and HCU.

## Accurate plant models from SimulationX

The plant models from SimulationX are accurate and represent the overall behavior of the complete vehicle, including all CAN signals and details of EMS, BMS, MCU control logic. The controllers can then be accurately checked and tuned against such plant models.

### Integration of calibration and measurements

Silver provides easy integration of in-vehicle measurements standard formats. This allows test engineers to provide data to function developers. Function developers can easily analyze problems met in the vehicle, define fix and corrections, and verify effects in the simulation.

### Integration of actual production c-code

During this project, we are currently integrating floating-point Simulink models. A next step will be the integration of actual production c-code, with fixed point arithmetic, tasks, along with A2L definition. The final production code used in the TCU and HCU can thus be fully tested, using Virtual ECUs.

### Control software Debugging in Silver

Simulink models built from Silver can access all internal signals and parameters of a model. This provides powerful function for debugging issues in control logic, arguably more comfortable and efficient than natively in Simulink.

## 5.2 Large coverage testing

Once an accurate/realistic virtual powertrain is available, it is possible to use it for large coverage testing using TestWeaver. QTronic TestWeaver can generate 1000's of test scenarios overnight and find problems and issues in the system. This increases system quality and system safety early in the development cycle. Compared to hand-written test scripts, TestWeaver scenario generation is a systematic process that will explore a large number of combinations and states.

In the case of the hybrid truck under consideration, state coverage objectives include gearshifts and hybrid mode transitions.

## 5.3 System optimization

The virtual powertrain established in the project can be used for system optimization, including control software optimization and calibration optimization. This work is efficiently supported since any function developer can introduce modifications and quickly get results on the new implementation. Moreover, Silver also supports scripting so that selected parameters can be automatically optimized using numerical optimization routines.

## 6 Conclusions

A virtual powertrain for a hybrid truck is being established in collaboration with Dongfeng Commercial Vehicles. For creating this system, several tools are being used, including ITI SimulationX, QTronic Silver and Matlab/Simulink.

The Virtual powertrain provides accurate simulation of the complete vehicle, down to gearshift synchronization events. Battery SOC and e-motor currents have been validated against in-vehicle measurements.

This Virtual Powertrain is applied for system optimization, HCU/TCU control logic debugging and large coverage testing with TestWeaver. These tasks can be conducted efficiently by engineers using PC-based deployable simulation.

## Abstract

The implementation of faults in Modelica is currently not standardized, which leads to many non-compatible implementations. To support the standardization of fault implementations, a new standard for fault implementation and triggering is proposed. The proposed standard can handle parameter faults as well as variable faults during a time simulation to cover all common fault possibilities. Using instance modifiers as well as an inner-outer broadcasting method, the faults can be triggered in a central block. Furthermore, care was taken so that the simulation of the models in a fault-free condition can be guaranteed. A library using the proposed standard was developed. In this library, the fault implementation as well as the triggering of these faults was modeled with the end user in mind. An example implementation is presented which shows the capabilities of the library.

*Keywords:* Failure, Fault, Modeling, Standardization, Fault Injection

## 1 Introduction

Failure detection and health monitoring systems to improve reliability and lower maintenance costs become increasingly important. Therefore the design and testing of these algorithms need good prediction models combined with an efficient way to trigger all fault cases.

Implementing faults in Modelica models is no new terrain. Many different implementations of real systems have been made. For example Schallert [8] did a reliability and safety assessment. The faults are automatically identified based on parameter names. To set the parameters of the failed parts, a function is used which automatically sets

the parameters before simulation. Gao et al. [3, 2] did a fault analysis of electrical systems. To trigger the faults, two different methods are used; hard coding a fault in the model as well as creating a completely new model for a fault. Cui et al. [1] modeled an actuator system with automatically triggered faults. This automatic triggering is based on the predefined fault probability, but cannot be directly controlled. These works are all examples where faults are triggered in a Modelica implementation. However, all of these implementations use different ways to trigger the faults. Since there is a lack of standards implementation ways, all users must find a way for them self to trigger the faults.

Another approach for model-based diagnosis is used by RODON [7]. Uncertainty intervals for the model parameters combined with behavioral models are used to trigger faults. However, time simulations are not supported which limits its use in many applications. Also FaultWeaver [6] can be used to trigger faults in Modelica. It uses a set of models in Modelica. An external (non-Modelica) program is used to set the faults in Modelica and simulate the results.

In this paper, a set of **standardized** fault-output blocks is proposed in Section 3. These blocks use a designated data type to clearly identify these blocks as special fault blocks for further processing. Using these blocks, it is possible to create component models which include optional faults by the user. Care has been taken to make sure that all possible faults can be modeled by a single or a combination of standardized fault blocks. By analyzing the complete model, built from individual sub-models, a wrapper package can be automatically generated which can be used to activate all faults (Section 5). Care has been taken that it is possible to completely eliminate the fault

code from a model to increase simulation performance if not all faults are triggered. Furthermore, also quick model testing without a fault setup is possible.

The proposed implementation is based on a Dymola implementation making use of the Abstract Syntax Tree (AST) functions from the `ModelManagement` library. By using the proposed **open** and **standardized** fault blocks with a specialized fault type, it is possible to create similar functionalities in all Modelica solvers.

## 2 Fault injection demands for Modelica

To create a general environment to trigger faults in Modelica, care must be taken that all possible faults can be modeled using the proposed blocks. To make sure all possible faults are covered, a trade off study has been carried out. Fault implementations in the Modelica language can be generalized into classes. The following sections will highlight the different fault classes.

### 2.1 Fault variability classes

For Modelica usage, two different classes of faults can be identified:

1. Faults that have a very low time constant with respect to the simulation horizon and can be considered constant.
2. Faults with time constants faster than the simulation horizon which will cause transient behavior.

To further clarify the classes, a more detailed description including examples of each fault class is given.

#### 2.1.1 Parameter faults

The parameter fault class consists of faults that have a low time constant compared with the simulation horizon. Usually these faults are characterized by slow changes in time such as the variation of the viscosity of oil due to an aging process in a transmission application. Another example of a fault with a slow time constant compared to the simulation time are some high frequency electronics simulations. In these simulations, the temperature of the environment can often be characterized

as constant. Some examples of parameter faults are:

- Gear play
- Degradation of capacitors or batteries
- Oil viscosity degradation in a transmission
- Environment temperature increase in a fast switching application

Due to the very slow nature of these faults with respect to their simulation time, it is not necessary to have the possibility to model fault transients.

#### 2.1.2 Variable faults

The second class of faults are variable faults. These faults are characterized by the possibility that they can significantly change during a typical simulation. Quite often the study of a transient response is one of the main purposes of the simulation of such faults. Some examples are:

- Semiconductor short circuit
- Breakage of hydraulic oil line
- Gearbox tooth breakage
- Screw jam

The faults in this class can vary during a simulation run, and can cause a dynamic system response which might be of interest for the engineer.

### 2.2 Fault data type classes

The faults of both classes described in Section 2.1, can be divided into three types to represent the different cases needed to model faults.

#### 2.2.1 "On-Off" faults (Boolean)

On off faults are marked by having only two discrete states. Examples are jamming of a nutscrew and disconnection of electrical cables.

#### 2.2.2 Case faults (Integer)

Case faults are marked by having multiple discrete failure modes. An good example is a semiconductor failure:

- Normal operation
- Short circuit
- Open loop

	Constant	Variable	Flag value	Description
<b>On-Off</b>	Increased friction	Screw jam	0	fault deactivated
<b>Mode</b>	Bearing fault mode	Transistor	1 (default)	standard fault mode activated
<b>Continuous</b>	Gear play	Oil loss	2,3,...	optional extra fault modes

Table 1: Combined fault possibilities for Modelica models with examples. The choice between a variable and parameter fault is not always directly clear, and may need to be chosen as constant or variable based on the length of the simulation

### 2.2.3 Continuous fault (Real)

A continuous fault is a fault without an explicit discrete value. Examples are:

- Oil degradation
- Increased friction in a bearing
- Capacitor degradation

Combining the fault classes (Section 2.1) and the fault class properties (Section 2.2), six different combinations of faults are identified (see Table 1). These possibilities can model all general and advanced faults. In the next sections, the implementation as well as some extra features for easier fault handling and simulation performance are discussed.

## 2.3 Variable mode selection

To accommodate the reconfiguration of a model with a variable fault, a mechanism to decide if the fault can be activated during simulation must be implemented. This reconfiguration can be necessary to increase simulation speed in case of no failure or to switch between different failure modes. In the case of a parameter fault, this is known by definition. However in the case of a variable fault, this is not known. To be able to reconfigure such a model, it is therefore necessary to add a parameter signal flag which can be used to reconfigure the model. For maximal flexibility, it is chosen to add a mode selection using an integer constant as a flag. This flag can be used to reconfigure a model to include or exclude a fault. How to use the values of the flag can be seen in Table 2.

The same effect as the mode selection is possible by combining a parameter integer fault with an variable fault. However, combining two fault inputs for one fault makes it hard to use consistent naming.

Table 2: Variable mode selection flag

## 3 Fault triggering standardisation architecture

Defining faults types is not sufficient to define a usable Modelica implementation. For a good user-friendly implementation a well designed architecture is vital. Different ways to set up a fault triggering method are analyzed and their benefits compared.

### 3.1 Fault Architecture

Controlling of the faults in a global model using components with faults can be done in many different ways. Different ways are studied in this section and it is decided which methods are selected for the proposed standard.

To assess the overall performance of these methods, a set of criteria is defined to evaluate several important aspects for fault triggering. The implementation effort of setting up the general architecture is not evaluated as this effort has to be invested only once in the generation of the fault library.

These criteria are:

- Non physical connections:** The connections between the models should be based on physical quantities. Faults do not have a physical connections as they are triggered by wear, or external influences which are usually not modeled.
- Ease of implementation:** Effort for user to create a model from instances using faults (e.g. the development of a multistage gearbox using predefined faulty gearbox instances)
- Maintainability:** Effort to maintain a set of models with faults. Typical tasks would be adding or removing fault cases, restructuring models and keeping a well documented set of models
- Standardization:** Standardization effort to keep models compatible between different

business partners.

- (e) **Transients:** Possibility to model transients used for variable faults (see for a description Section 2.1.2).

Four methods to implement faults in Modelica have been tried out and analyzed. The results are assessed using the criteria (a through e).

1. **Model parameters:** Each fault is controlled by a parameter in the model. It is possible to "pull" these parameters up to the top level model. Also direct changing of the instance parameter in the model is possible. If the parameter is flagged appropriately, it is possible to create a system with automated parameter detection and central setting of the parameters. Such a structure does not need non-physical connections, is easy to implement for the user and, if a proper automation is used, can be well maintained. Also standardization using the proposed flag methods is possible. Since in this method it is only possible to handle parameters, no transients can be used.
2. **Model inputs:** Inputs are used to control faults in the models. By connecting the input connectors, it is possible to create a central element to control all faults. This method is often used for small fault systems. However, it leads to non physical connections between the models. Due to the high customization, maintainability and standardization cannot be guaranteed. The ease of implementation is good in small systems maintained by a single person, but quickly becomes more and more problematic as the model grows. Transients can be handled well.
3. **Bus system:** A bus system to connect faults. All fault signals are connected to a bus system. This way is similar to the model inputs, except that all faults are organized in one block. A bus system leads to non physical connections. The ease of implementation and maintainability depends highly on the complexity of the model, small systems can be easily implemented and managed, but it become quickly confusing. The standardization is better than using a direct model input since all faults are now marked in one fault-bus. However, still no automated algorithms can be used as it is impossible to properly

define a standard input. Transients can be handled well as it is possible to connect variables to a bus.

4. **Broadcasting:** Using an inner-outer structure, the fault models can obtain their values from a centralized point in the global model. Using an automated routine, all appropriate flagged faults can be found and managed in one central point. No non-physical connections are needed. If standardized, flagged and predefined fault blocks are used, the ease of implementation and maintainability is high. Also the standardization can be guaranteed by flagging the models. Using an inner-outer structure it is also possible to use transients. However, when only parameter Faults are used, this way of modeling is over complex and will always need a full setup of the variable faults. In contrast, it is possible to leave most parameter faults at their standard value and set only one fault without setting up a complete fault system.

In Table 3, the previously discussed four different approaches (1:4) are assessed using the criteria (a:e). From this analysis follows that the usage of model parameters (1) and a broadcasting system (4) have most advantages. It is therefore chosen to use following architecture:

- **Model parameters** to handle **constant** faults
- **Broadcasting system** for **variable** faults

## 4 Standardized fault class definition

All faults in a model must be recognized by automated scripts, while at the same time the user should have the freedom to name the model faults arbitrarily. To do so, special fault classes have been designed. This has the advantage that a fault is identified by the class name, and can be integrated without special care of instance names by the user. These fault classes are released under the Modelica 2 License.

Below the all fault classes are defined. For a parameter fault of the type Real, the type is defined in Code 1.

Description	(a) Non physical connections	(b) Ease of implementation	(c) Maintainability	(d) Standardization	(e) Transients
(1) Model parameters	+	+	+	+	-
(2) Model inputs	-	$\pm$	-	-	+
(3) Bus system	-	$\pm$	$\pm$	$\pm$	+
(4) Broadcasting system	+	$\pm$	+	+	+

Table 3: Fault triggering approaches. A detailed description of the criteria can be found in Section 3.1

Code 1: Real parameter fault

```
type Parameter_Fault_Real =
  Real "Value of the Real Fault";
```

Using this special fault class for each Real fault, it is possible to clearly identify each instance of this model as a Real parameter fault.

The same is done for variable faults. Since these faults are more complex, a record with three parameters is used. In Code 2 the definition of this Fault is shown.

Code 2: Real variable fault

```
record Variable_Fault_Real
  "External Fault Triggering parameters"
  Boolean externalFaultOn=false
  "External fault controlling
  (true = global)";
  Integer faultIndex = 1
  "External fault index";
  Integer faultMode = 1
  "Optional fault mode for model
  reconfiguration";
end Variable_Fault_Real;
```

The first Boolean `externalFaultOn` is used to switch between the local default fault definitions and external global control. The integer `faultIndex` is used to set the channel in the external global fault triggering (see Section 5). The Integer `faultMode` is used to set the optional fault mode selection as discussed in Section 2.3.

The examples given in this section are for Real faults. The code for Integer and Boolean faults can be found in Appendix A.

Using these class definitions, it is possible to set up a complete fault triggering system. In Section 5 an implementation for Dymola using the Model-Management toolbox is presented. Since these defined faultclasses are open and standardized, algorithms or plug-ins for programs can be developed by users, also for other Modelica solvers.

## 5 FaultTriggering library

Beside the definition of a standard, a library has been built to support the user with implementing faults. Using the definitions from Section 4, blocks are created which simplify the implementation of faults in a model. Two versions of these outputs are made; one for textual modeling and one for usage in the diagram layer. Also a method to manage the fault signals in a single block is proposed.

In Figure 1, an overview of the final fault setting structure is given. In the generated wrapper model, it is possible to set the parameter and variable faults. The parameters are set in an automatically generated structure (see Section 5.3.2) and the variable faults are handled using a generated bus system (see Section 5.3.3).

### 5.1 Parameter fault modeling

The textual modeling block for a parameter fault is a simple block with a parameter of type `Parameter_Fault_Real` (for Real faults). By extending this block in the model, a parameter fault is directly correctly implemented and its name is `constRealFault`.

In Code 3 the code for the Real parameter fault is given. Parts of the complete path to the components are abbreviated for a better overview. Integer and Boolean faults are implemented using the same approach.

Code 3: Real parameter fault for textual modeling

```
block InternalConstantRealFault
  "Generate constant Fault of type Real"
  extends ...Icons.RealFault;
  parameter ...Types.Parameter_Fault_Real
    constRealFault= 1
    "Constant output value";
end InternalConstantRealFault;
```

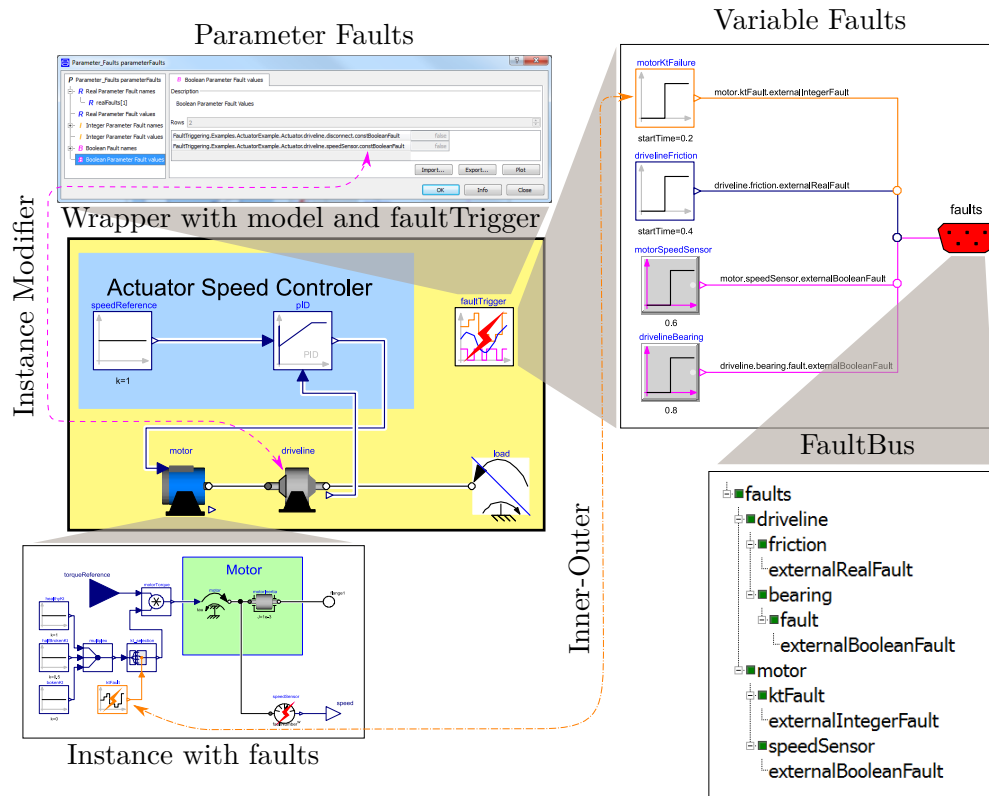

Figure 1: Automatically generated wrapper model (yellow) which contains the extended original model and the block `faultTrigger`. In this block all parameter and variable faults can be set. The parameter faults communicate directly with the model instances using instance modifiers (pink dash-dotted line), the variable faults using a bus system connected to a global inner/ outer system (orange dashed line).

The blocks for graphical modeling environment are extensions of the discussed textual modeling approach and the interface `Modelica.Blocks.Interfaces.S0`. This creates a block (see Code 4) with a single Real output whose value is set by the fault parameter.

Code 4: Real parameter fault for graphical modeling

```
block ConstantRealFault
  "Generate constant signal of type Real"
  extends Modelica.Blocks.Interfaces.S0;
  extends ...InternalConstantRealFault;
  equation
    y = constRealFault;
  end ConstantRealFault;
```

## 5.2 Variable faults

The variable fault blocks are more complicated to implement than the parameter fault blocks. These blocks need the information from a central block in which the fault signal is defined. To do so an inner-outer structure has been set up to communicate the fault signals. In this section, first the global

block will be discussed followed by the local fault blocks.

### 5.2.1 Global variable faults control

For each variable fault (Real, Integer and Boolean), a single channel is reserved in a variable with  $n$  channels (with  $n$  the number of faults of each type). This variable is defined in a central `FaultTrigger` block extended from `...FaultOutput.Partial_FaultTrigger`. Each fault can be coupled to fault sources using modelica code in this global block. This can be done by hand or an automated script which is proposed in Section 5.3.3. The partial model can be seen in Code 5. This model is defined as "inner" in the annotations, so that the local fault injection blocks can communicate with this block.

Code 5: Partial model for variable fault input framework

```
partial model Partial_FaultTrigger
  "partial model defining fault classes"
  parameter Integer realFaultSize
    "Number of real fault channels";
```

```

parameter Integer integerFaultSize
  "Number of integer fault channels";
parameter Integer booleanFaultSize
  "Number of boolean fault channels";

Real    realFault[realFaultSize]
  "Real Fault trigger";
Integer integerFault[integerFaultSize]
  "Integer Fault trigger";
Boolean booleanFault[booleanFaultSize]
  "Boolean Fault trigger";

annotation (
  defaultComponentPrefixes="inner")
end Partial_FaultTrigger;

```

### 5.2.2 Variable fault modeling classes

The variable fault models get their signals from the global fault control model. In Code 6 the code for a variable fault is given. In this model, the variable fault is the actual fault value. Each fault uses its own fault channel in the variables `realFault`, `integerFault` and `booleanFault`. To select which channel is to be used from these variables, the parameter `faultNumber` is defined. This parameter is generally set by an automated system (see Section 5.3.3).

To be able to directly operate a model with variable faults in the model for testing purposes, a parameter with a default fault value is defined in `fault_local`. Using the switch (`externalRealFault.externalFaultOn`), the local fault can be changed to the value defined in the global fault block. Using this, it is guaranteed that each block has a valid output without setting up a global fault block.

Code 6: Real variable fault for textual modeling

```

block InternalRealFault
  "Generate variable Fault of type Real"
  extends ...Icons.RealFault;
  outer FaultTrigger faultTrigger;
  parameter Real fault_local = 1
    "Default fault value if no external
    triggering is used";
  parameter ...Types.Variable_Fault_Real
    externalRealFault =
    ...Types.Variable_Fault_Real()
    "External Fault Triggering parameters";
  Modelica.Blocks.Interfaces.RealOutput
    fault "Final fault value";

protected
  ...Types.Fault_SelectRealFault
    faultNumber;
equation

```

```

faultNumber =
  externalRealFault.faultIndex;
fault =
  if externalRealFault.externalFaultOn
  then
    faultTrigger.realFault[faultNumber]
  else fault_local;
end InternalRealFault;

```

The faults for graphical modeling are made by extending Code 6 in a model with two outputs (Code 7): One real output for the fault signal and one optional integer output for the mode signal.

Code 7: Real variable fault for graphical modeling

```

block VariableRealFault
  "Generate variable signal of type Real"
  extends ...Internal.InternalRealFault;
  parameter Boolean useModelModeSelection
    "toggles external mode selection";
  Modelica.Blocks.Interfaces.RealOutput y;
  Modelica.Blocks.Interfaces.IntegerOutput
    mode = externalRealFault.faultMode
    if useModelModeSelection
    "Connector of Integer output signal";
equation
  y = fault;
end VariableRealFault;

```

## 5.3 Automated fault handling

To keep overview of the faults in a model and help the user with fault channel selection for each fault, an automated fault handling algorithm is developed. This algorithm can detect the parameter and variable faults in the selected model. Also all faults in the instances used in this model can be detected. Setting and internal handling of these faults is different for parameter and variable faults. A library is automatically generated which contains a wrapper model that extends the original model. Also a central block to manage the faults is instantiated in this wrapper model. In this block, the configuration of the parameter and variable faults is handled.

### 5.3.1 Automated fault finding

Using the Dymola ModelManagement toolbox, it is possible to investigate a model with its sub-models. Using these features, it is possible to generate a model tree from a model with all instances. A schematical example of such a model tree can be found in Figure 2. Using the type definitions from Section 4, all faults in a model can be found and

Figure 2: Model tree with faulty models on several levels. Blocks with a lightning symbol (A.A & A.C.B) are extensions of the standardized fault classes.

classified. Also the "path" to the model can be found. The complete path of the fault instance `bearing_stuck` in the model `Actuator` will be represented as `Actuator.bearing_stuck`. In the following sections, the generated fault tree and fault classification will be used in the implementation of the library features.

### 5.3.2 Global parameter setting

All the parameter faults can be found and identified using a method described in Section 5.3.1. It is possible to directly change these values by using an instance modifier generated by the fault-search algorithm by hand.

However, in case of large models with many faults or many different cases to analyze, this can quickly become unclear and tedious. To aid the user, a structure is automatically generated using the scripts supplied in the library which includes all faults together with their default values. This structure is used as a parameter in the global `faultTriggering` model. These values are automatically linked to the instance modifiers in the wrapper model. By creating different fault structures, fault cases can be defined. Each fault structure stands for a clearly defined simulation case.

### 5.3.3 Global variable setting

To aid the user with setting the variable faults, a hierarchical `faultbus` is generated from the fault structure (see Figure 1). It is possible to directly connect the fault source signals to the hierarchical bus. The hierarchical bus system itself is connected to the `realFault`, `integerFault` and `booleanFault` variables (see Section 5.2.2). The corresponding fault index is automatically set in

Figure 3: Automatically generated Fault library

the model using component modifiers. Using this approach, mistakes with mixing up the channels are not possible, as this is automated. Also the use of an automatically generated bus makes connecting the fault sources easy.

In Figure 3, a generated library is shown with its default components.

## 6 Examples

To test the library functionality a simple actuator model is built consisting of a motor with PID control, a simple driveline and a load. The total model has 6 faults: 2 parameter faults, and 4 variable faults. Using the fault processing algorithms presented in Section 5.3, a package is generated. The model wrapper adds the `faultTrigger` block in which all faults can be set. In this block all fault inputs are defined. The variable faults are set in the block of type `FaultTriggerController` (instance `faultTrigger`). Using the parameter record in this block, it is possible to set all parameter faults. An overview of this functionality is shown in Figure 1.

The result of a simulation with progressive faults is shown in Figure 4. The dynamic effects of a breaking component can be seen by the changing response of motor speed and torque. By changing or duplicating the `faultTrigger` block, it is possible to create multiple fault scenarios for a single model. The original model stays unchanged and can be used for all analysis, healthy as well as broken.

## 7 Conclusion and Discussion

In this paper, a method to standardize the implementation of faulty components in Modelica is specified. It is possible to implement parameter, as well as varying fault signals. The code for the proposed faulty components is included to aid the

Figure 4: Results of a simulation with progressive faults. At  $t=0.2$ s the motor constant drops, at  $t=0.4$ s, an increased friction in the driveline is triggered, at  $t=0.6$ s, the speed sensor of the motor breaks and finally at  $t=0.8$ s the driveline bearing gets stuck.

standardisation of fault implementation in Modelica.

Moreover a library has been created which supports the user to set these faults by automatic generation of a wrapper library. This wrapper includes all parameter faults in a parameter structure and a bus system to connect the variable faults. This functionality is enabled by the implementation of a search algorithm to search the model for the standardized fault classes.

An example model has been built and the methods to implement the faults in the model have been proved valuable. At the moment the proposed Fault Library is used in the Actuator EMA library [4, 5, 9]. The standardization of these faults has led to an easy implementation process. The model designer can focus on implementing the faults in the model without paying attention to the interfaces and the compatibility between the models.

## Acknowledgement

The research leading to these results has received funding from the European Union's Seventh

Framework Program (FP7-284916) for ACTUATION 2015 under grant agreement no. 284915.

## A Modelica Code for Faults

The code for the implementation of the fault classes is given in this section. Using strictly this code, it is possible for automated fault systems to search for all faults in a model.

### A.1 Real faults

Code 8: Real parameter fault

```
type Parameter_Fault_Real =  
  Real "Value of the Real Fault";
```

Code 9: Real variable fault

```
record Variable_Fault_Real  
  "External Fault Triggering parameters"  
  Boolean externalFaultOn=false  
  "External fault controlling  
    (true = global)";  
  Integer faultIndex = 1  
  "External fault index";  
  Integer faultMode = 1  
  "Optional fault mode for model  
    reconfiguration";  
end Variable_Fault_Real;
```

### A.2 Integer faults

Code 10: Integer parameter fault

```
type Parameter_Fault_Integer =  
  Integer "Value of the Integer Fault";
```

## Abstract

We propose a model-based diagnosis framework in which Modelica models of faulted behavior are used in combination with a Bayesian approach. The fault augmented models are automatically generated through a process developed as part of our Fault Augmented Model Extension (FAME) work. Fault diagnosis using a Bayesian approach is based on computing a set of probability density functions, a process that is usually intractable for any reasonably complex system. We use Approximate Bayesian Computation (ABC) to bound the numerical and computational complexity. The basic idea is to use fault augmented Modelica models to create probability distributions of possible outcomes and then compare those distributions against actual observations to perform parameter estimation. The detection of faults is treated as a model selection problem and the inference of their severity levels is treated as parameter estimation. The diagnostic precision of this approach is evaluated on a Modelica vehicle drive line model.

*Keywords: fault models; diagnosis; machine learning; model translation; bayesian methods*

## 1 Introduction

Modelica [6] is an object-oriented, declarative, multi-domain modeling language for component-oriented modeling of complex systems. It is used to execute numerical simulations to determine the behavior of a system. This approach frees the designer to efficiently explore a wide set of designs to see which meets customer requirements, without needing to physically construct the systems.

In addition to predicting behaviors through numerical simulations of Modelica models, we propose to use the same simulation models for diagnosis. Modelica's focus on simulation would seem to make it a

poor choice for diagnosis. After all, diagnosis is the inverse of simulation. Simulation predicts the behavior of a system given a (correct) model. Diagnosis must infer how the model has changed (i.e., faulted) from observed behavior.

Most model-based diagnosis algorithms [4, 10] perform inference on declarative models. Although Modelica supports the writing of declarative models, too many Modelica models (including many in the MSL) contain imperative constructs making direct application of existing model-based diagnosis algorithms problematic. RODON [2] is a Modelica inspired approach to modeling, but Modelica models first have to be re-written by hand in qualitative declarative form. We know of no system identification or FDI technique that applies for DAE models with boolean constraints (as Modelica models translate into). Our approach, on the other hand, applies on Modelica models directly no matter what types of constraints they contain.

This paper presents a framework for model-based diagnosis in which Modelica tools play a fundamental inference role in a Bayesian approach. Numerical simulations of Modelica models are used to build statistical models for the behavior of a system for all of its fault-operating modes; statistical models that help determine a diagnosis solution based on observations.

The simulation of a system under different fault-operating modes is enabled by fault-augmented Modelica libraries. As part of our Fault Augmented Model Extension (FAME) work, we have developed an approach [5] for automatic model construction of Modelica fault models. Our model fault-augmentation approach is based on analyzing Modelica libraries for fault susceptibility and on modifying them to enable simulation of faulty components. FAME provides the set of possible faulted behaviors for each component (e.g., a resistor might be open, shorted, or resistance shifted by some undetermined amount). FAME can use as input statistical models from reliability analysis that determine the fault activations and the amount

of change in the values of the parameters.

Consider a grossly simplified vehicle model illustrated in the Modelica model of Figure 1. The brake may be working normally (Nominal state) or may be having friction related faults (Slipping or Sticking). The severity of these fault modes is modeled in Modelica by a parameter called `amount`  $\in [0,1]$  where a value of 0 indicates no fault (i.e., Nominal state) and a value of 1 indicates total failure. The part will likely be unusable (and hence considered faulty) for values far less than 1.

When the brake absolute angular velocity  $\omega$  is not zero, the frictional torque applied by the brake is a function of a velocity dependent friction coefficient  $\mu(\omega)$ , the normal force  $f_n$ , and of a geometry constant  $c_{geo}$ , which takes into account the geometry of the device and the assumptions on the friction distributions:

$$\tau = c_{geo} \times \mu(\omega) \times f_n.$$

Our approach can be used to estimate such parameters in addition to performing diagnostics. For this exercise, we assume that the only unknown parameter is the `amount` but we could just as easily estimate the other parameters such as  $c_{geo}$  and  $f_n$  from the observed data.

## 2 FAME approach

We have developed faultable models for the models in the Modelica Standard Library. A detailed description of FAME can be found in [5], while [8] describes how it can be used in a design-tool chain to perform reliability analysis. Here we summarize the essential details of FAME for the purpose of diagnosis. Every model class definition which contains faults is replaced with a new class definition, a Modelica model class subsuming the original model class and adding declarative behavior to allow simulation of the faults.

An encapsulated enumerated type is defined, listing the various fault modes of the class, along with the Nominal mode. A discrete mode parameter of this new type is introduced, defining the mode in which an instance of the class is operating. An if-equation similar to Figure 2 is added, so that each operating mode can define its own dynamics.

The set of equations which apply in each fault mode is expressed in the appropriate branch of this if-equation. The process also flattens the superclasses of the model into the rewritten class, and introduces two new externally visible parameters, `mode` and

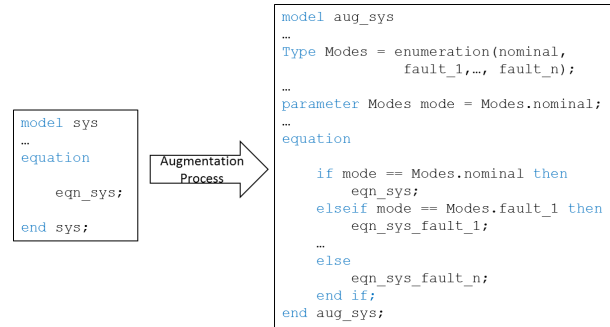

Figure 2: Alternative dynamics are enabled for each operating mode.

`amount`, as well as an enumerated type giving the possible faults for this component, `Modes`.

Modelica models are augmented with two types of faults: *power faults* and *parametric faults*. Power faults model loss of power at the connection points and is implemented through the addition of new components abstractly called “dampers” that implement this behavior. We show below how the `Stick` fault is implemented at `flange_a` of the `Brake` component:

```

model Brake
...
Modelica.Mechanics.Rotational.
    Interfaces.Flange_a flange_a;
FAME.Dampers.RotationalWithConnectEquations
    _famefault_flange_a(amount=0.0);
...
end Brake

model RotationalWithConnectEquations
    input Real amount(min=0.0, max=1.0);
    encapsulated type Modes = enumeration(
        Nominal,
        Stick,
        Broken);
    parameter Modes mode = Modes.Nominal;
    Modelica.Mechanics.Rotational.
        Interfaces.Flange_a port_a;
    Modelica.Mechanics.Rotational.
        Interfaces.Flange_a port_b;
    equation
        ...
        elseif mode == Modes.Stick then
            port_b.tau + port_a.tau =
                (1/max(Constants.verySmall,1-amount)-1)
                *der(port_a.phi);
            port_b.phi = port_a.phi;
        else
            ...
        end if;
    end RotationalWithConnectEquations;

```

We note that a new component called `_famefault_flange_a` was added to the `Brake` model; component that implements the behavior corresponding to the `Stick` fault.

Figure 1: Simple drive line.

Similarly, parametric faults are handled by introducing a new component that defines the pattern of change for the parameter to which this component is associated. For example in the case of the Brake model, `_famefault_mue_pos` is an instance of the newly added `_famefaults_mue_pos` component that corresponds to the `mue_pos` parameter:

```
model Brake
  model _famefaults_mue_pos
    extends FAME.Parametric.
    BaseParametricFault(amount=0.0);
    type Modes = enumeration(
      Nominal,
      Slip);
    parameter Modes mode=Modes.Nominal;
    equation
    if mode==Modes.Slip then
      y = u*{{1,0},{0,1-amount}};
    else
      y = u;
    end if;
  end _famefaults_mue_pos;
  ...
  _famefaults_mue_pos _famefault_mue_pos
    (u=mue_pos, redeclare type
    ParamType = Real[size(mue_pos,1),2]);
  ...
end Brake;
```

References to the original parameter are replaced with an expression which references to this new variable. For example, the parameter `mue_pos` is replaced in the fault-augmented version of the Brake by `_famefault_mue_pos.y`.

We consider several other fault modes. Consider the simple spring-damper system of Figure 3. Figure 4

Figure 3: Spring Damper example.

shows three simulation results for the Nominal,

Stick and Broken modes for `inertial1`. The underlying intuition of our approach is to pre-compute many simulations under many fault scenarios and perform on-line diagnosis by identifying the pre-computed simulation results which best matches the observation. In the remainder of this paper we describe how this intuition has been implemented.

Figure 4: Nominal, Stick and Broken operating modes for the spring-damper system

### 3 Fault detection in the drivetrain system

We demonstrate our proposed approach by detecting faults in the drivetrain system shown in Figure 1. We model five failure modes: brake slipping, brake sticking, clutch slipping, clutch sticking, and spring sticking. The failure mode of a stuck brake is modeled in the FAME library as a dynamic damper component that adds damping equal to the `amount`<sup>1</sup>. This has the effect of increasing the relative friction in the flanges which results in a loss of power. The failure mode of a slipping brake is modeled as a decrease in the velocity dependent friction coefficient by an amount equal to the severity of the fault:

$$\mu(\omega) \mapsto \mu(\omega) \times (1 - \text{amount}).$$

<sup>1</sup>Under normal operating conditions, the `amount` = 0 so the system does not experience this additional damping.

This has the effect of reducing the friction torque<sup>2</sup>. The other failure modes are modeled in a similar manner. Our aim is to infer from observed data whether the system is exhibiting a fault mode — if so, we also need to infer the severity of the fault (i.e., the value of amount). We achieve this by using ideas developed for Approximate Bayesian Computation (ABC).

## 4 Approximate Bayesian Computation

Modelica models are formal representations of (hybrid) differential equations (DAEs). Existing results on fault diagnosis of DAEs are not able to cope with such mathematical models in their generality. They either focus on the structural aspect of the system, ignoring its dynamics [7], or they make simplifying assumptions, such as linearity, on the DAE model [3]. Therefore more practical approaches for fault diagnosis must be employed.

In this section, we give an overview of the ABC method, based on material from [9, 12, 1] — see those references for more details. The typical tasks are to estimate unknown model parameters and to do model selection. Let  $M$  be a model parameterized by some parameters  $\Theta$  whose joint prior density is  $\pi(\Theta)$ . Given data  $d$  generated by the model  $M$ , we are interested in estimating the posterior probability  $\pi(\Theta|d)$ . From Bayes rule, we know that

$$\pi(\Theta|d) \propto f(d|\Theta)\pi(\Theta),$$

where  $f(d|\Theta)$  is the likelihood of the data given the parameters. The prior probability of the parameters is known so we need to compute the likelihood of the data in order to estimate the posterior probability of the parameters. A similar approach can be used for model selection. Let  $M_1$  and  $M_2$  be two models and we would like to infer which of them is more likely to have generated the given data  $d$ . Using the Bayesian analysis framework, we compute the Bayes factor  $B_{12}$  to summarize the evidence provided by the data for model  $M_1$  over model  $M_2$ :

$$B_{12} = \frac{P(M_1|d)/P(M_2|d)}{P(M_1)/P(M_2)},$$

where  $P(M_i)$  is the prior probability of model  $M_i$  and  $P(M_i|d)$  is the posterior probability of the model  $M_i$  given the data  $d$ . A value of  $B_{12}$  between 1 and 3

suggests weak evidence in favor of  $M_1$ , a value between 3 and 20 suggests positive evidence, a value between 20 and 150 suggests strong evidence, and a value greater than 150 suggests very strong evidence. The prior probabilities of the models don't depend on the given data and can be pre-computed. So computing the Bayes factor comes down to computing the ratio of the posterior probabilities of the models given the data:

$$B_{12} \propto \frac{P(M_1|d)}{P(M_2|d)} \propto \frac{f(d|\Theta_1)}{f(d|\Theta_2)}.$$

For any reasonably complex model, the likelihood computation is intractable so ABC approaches like rejection are used to approximate it. In order to simplify the problem computationally, it is common to define a function  $f_s : \mathbb{R}^n \rightarrow \mathbb{R}^m$  that maps the given data  $d \in \mathbb{R}^n$  to some representative statistic  $s \in \mathbb{R}^m$  where  $m \ll n$ . Then we define a distance metric  $dist_s : \mathbb{R}^m \times \mathbb{R}^m \rightarrow \mathbb{R}$  to measure closeness of two sets of statistics. Let  $\hat{d}_{M_i}$  be simulated data generated from a model  $M_i$ .

### 4.1 Rejection Technique

If  $dist_s(f_s(d), f_s(\hat{d}_{M_i})) < \varepsilon$  for some threshold  $\varepsilon$  then the simulated data is accepted for the given observed data  $d$  — otherwise, it is rejected. Now assume that we generate  $N$  data sets simulated from the model  $M_i$  as follows. For each of the  $N$  iterations, draw a parameter vector  $\Theta_i$  from the prior distribution  $\pi(\Theta_i)$  and simulate data  $d_s^i$  from  $M_i$ . Assume that  $\bar{N}$  of those simulated data sets are accepted given a threshold  $\varepsilon$ . Then we can approximate  $P(M_i|d)$  as  $\frac{\bar{N}}{N}$ . The distribution of the  $\Theta_i$  for each of the accepted iteration approaches  $\pi(\Theta_i|d)$ . The approximated values approach the true values asymptotically as  $N \rightarrow \infty$  and  $\varepsilon \rightarrow 0$  if the statistics are sufficient to describe the data. The downside of this approach is that if  $\varepsilon$  is small then  $N$  needs to be high in order to achieve a reasonable approximation. In other words, it can be very computationally expensive.

### 4.2 Classification Technique (alternative approach)

For model selection, rather than computing the ratio of posterior probabilities, we could use a classification approach instead. Here we treat the model indicator  $i$  as the response variable and the summary statistics as the dependent variables. Any standard classification technique such as multinomial logistic regression, random forest, neural network etc. can be used

<sup>2</sup>Again, under normal operating condition, the amount = 0 so the system does not experience this loss in torque.

to train a model based on the simulation data.<sup>3</sup> The trained model is evaluated on the statistics  $f_s(d)$  of the observed data to directly estimate  $P(M_i|d)$ . This approach may be needed for more complex diagnostic tasks, but as the rejection approach performs so well, we use it in our example.

## 5 Evaluating the approach

The first step in ABC is to generate a large number of simulations. To constrain the problem appropriately, we assume that the observed output of the system is generated in response to a known input. For example, the response of a dynamical system to a step input (called a step response) is typically used to reason about the system behavior and may be appropriate for diagnosis as well. This choice is part of the feature selection and needs to be made at the time of diagnostic design. For each of the five fault modes, we generate 10,000 step-response simulations<sup>4</sup> — we first sample the `amount` from its prior distribution<sup>5</sup> and then use that value to perform the simulation. This was done by parameterizing the variables in Modelica file — a snippet of the Modelica model is shown below — the string `FAULT_AMOUNT` is replaced with the sampled value before running a simulation.

```
Brake brake(fnmax = 1600,
  _famefault_mue_pos(mode = Modes.Slip,
    amount=FAULT_AMOUNT);
```

The second step in ABC is to compare observed data against the simulated data. For computational reasons, we compare features computed from the simulated and actual data rather than comparing the raw data directly. For this exercise, we evaluate the step response of the drive train system and compute the following features of the absolute angular velocity of the inertial load connected to the brake: (1) mean, (2) maximum, (3) 25<sup>th</sup> percentile, (4) 50<sup>th</sup> percentile, (5) 75<sup>th</sup> percentile, (6) inter-quartile range, and (7) time to go to zero. The values of these seven features can be thought of as a vector of dimension seven. The difference between the observed vector and the simulated vectors is used to compute an estimate of the

<sup>3</sup>Any technique that returns a normalized measure of classification should be usable.

<sup>4</sup>For a more complex model, we may need to generate a higher number of simulations.

<sup>5</sup>For this example, we sample `amount` from a uniform distribution:  $\text{amount} \sim U(0.003, 0.5)$ . In practice, the choice of this distribution will depend on the belief of the designers about the distribution of the fault amount — such a distribution may be learnt from field performance data of similar systems. This is a typical design choice in Bayesian analysis and a non-informative distribution such as a uniform distribution may be used if no other source of information is available.

likelihood that the observed value was generated from the simulated distribution. For more details, please see [11].

In order to evaluate the effectiveness of our approach, we measure the diagnostic accuracy of detection the following 11 faults.

1. *Brake Slipping* fault mode with `amount=0.1`
2. *Brake Slipping* fault mode with `amount=0.25`
3. *Brake Sticking* fault mode with `amount=0.1`
4. *Brake Sticking* fault mode with `amount=0.25`
5. *Clutch Slipping* fault mode with `amount=0.1`
6. *Clutch Slipping* fault mode with `amount=0.25`
7. *Clutch Sticking* fault mode with `amount=0.1`
8. *Clutch Sticking* fault mode with `amount=0.25`
9. *Spring Sticking* fault mode with `amount=0.1`
10. *Spring Sticking* fault mode with `amount=0.25`
11. *Nominal* mode (i.e., with no fault mode or a fault mode with a very small `amount`)

For each of these faults, we infer the fault model that was most likely to have generated it and estimate the `amount`. The analysis was done using the *ABCToolbox* suite [11].

## Results

We first show how each model fares against the observed data and then put it all together to generate the final diagnosis.

### *Brake Slipping* model

When the eleven faulty behaviors are compared against the simulations from the *Brake Slipping* model, the marginal distribution of the model is nearly zero for all but faults #1, #2 and #11. The graphs below show the posterior density distributions of `amount` for those three faults — as the graph shows, the inference is correct and the estimate of the `amount` is also very accurate. Of course, in order to make the final diagnosis for a fault, the marginal density for this model will need to be compared against the densities for the other models.

### Brake Sticking model

When the eleven faulty observations are compared against the simulations from the *Brake Sticking* model, the marginal distribution of the model is nearly zero for all but faults #3, #4, and #11. The graph below shows the posterior probability distributions of `amount` for those three faults — again, the inference is correct and the estimate of the amount is also very accurate.

### Clutch Slipping model

When the eleven faulty observations are compared against the simulations from the *Clutch Slipping* model, the marginal distribution of the model is nearly zero for all but faults #5, and #6. The graph below shows the posterior probability distributions of `amount` for those two faults — while the distributions are not as peaked as the ones for brakes, the inference is still correct and the mode of the distribution is over the correct value of `amount`.

### Clutch Sticking model

When the eleven faulty observations are compared against the simulations from the *Clutch Sticking* model, the marginal distribution of the model is nearly zero for all but faults #3, #7, #8, #9, and #11. In this case, the marginal distribution is non-zero for two faults (#3 and #9) that do not correspond to the clutch sticking failure mode. However, the overall diagnosis still turns out to be correct because the marginal distribution numbers for the correct models are much higher than these numbers (see Section 5). The graph below shows the posterior probability distributions of `amount` for faulty observations #7, #8, and #11 — as in the other cases, the posterior distributions of `amount` have very narrow peaks over the correct values.

### Spring Sticking model

When the eleven faulty observations are compared against the simulations from the *Spring Sticking* model, the marginal distribution of the model is nearly

zero for all but faults #9, #10, and #11. The graphs below show the posterior probability distributions of amount for those faults — again, both the fault mode inferences and the estimates of amount are correct.

### Final diagnosis

As mentioned previously, all the faulty observations except #3, #9 and #11 are inferred to have a single (and the correct) cause. While fault #11 (which corresponds to the normal operation) has significant ambiguity regarding the cause, the inferred amount is always nearly zero in all those cases — this correctly indicates the absence of any fault mode. In other words, fault #11 is correctly associated with normal operation. Fault #3 is inferred to have been generated by either *Brake Sticking* or *Clutch Sticking* failure modes. Similarly, fault #9 is inferred to have been generated by either *Clutch Sticking* or *Spring Sticking* failure modes. So for these two cases, we need to look at the ratios of the respective posterior densities, i.e., compute the Bayes factor in order to complete the diagnosis (see Section 4 for more details).

**Fault #3** For this fault, the marginal posterior density of *Brake Sticking* model is  $9.8 \times 10^9$  while that of *Clutch Sticking* model is 1.7. So the Bayes factor for *Brake Sticking* is  $\frac{9.8 \times 10^9}{1.7} = 5.7 \times 10^9$  which is very strong evidence in favor of *Brake Sticking* (i.e., the correct diagnosis).

**Fault #9** For this fault, the marginal posterior density of *Clutch Sticking* model is  $3.6 \times 10^3$  while that of *Spring Sticking* model is  $2.9 \times 10^8$ . So the Bayes factor for *Spring Sticking* is  $\frac{2.9 \times 10^8}{3.6 \times 10^3} = 8 \times 10^4$  which is very strong evidence in favor of *Spring Sticking* (i.e., the correct diagnosis).

So the FAME based inference approach is able to make the correct diagnosis for all the faults.

## 6 Final remarks

This paper has demonstrated that a straight-forward application of machine learning techniques to simulation can be used to accurately diagnose systems. In fact, it can diagnose systems even if some of the (non-faulted) parameters are unknown. This approach has some inherent limitations: (1) the expansion to multiple faults will require exponentially more pre-computed simulations and therefore would only scale to simple systems, (2) active diagnosis will require deriving features for many system variables which may be impractical, (3) the features (i.e. sufficient statistics of the signal) we use are somewhat determined by the requirements of the system and must be determined at the outset, and (4) if the system can have a wide variety of exogenous inputs, too many pre-computed simulations will be required in order to diagnose for each possible input stream.

The expansion to multiple faults can be ameliorated somewhat by the fact that the simulations are done offline and can be easily parallelized. This complexity may be further managed if a reasonable assumption can be made about an upper limit on the number of simultaneous faults (thereby reducing the complexity from exponential to polynomial).

## Abstract

This paper presents a methodology for model-based fault detection and diagnosis underpinned by modelica models and using a qualitative approach to diagnosis, which has been applied to diagnosis of an air handling unit based on data recorded by a building management system. The main steps from model development to component diagnosis are discussed and illustrated using a heating coil component.

*Keywords: model-based diagnosis, heating coil, calibration, fault detection and diagnosis*

## 1 Introduction

Heating Ventilation and Air conditioning (HVAC) systems are known for being very inefficient for different reasons, one of the most common causes being the presence of undetected failures in one or more of its components. Undetected faults can remain for long periods due to different factors: compensations made by the control algorithms of other elements belonging to the same system; lack of proper maintenance, improper timing of flow of energy to/from the building, etc. Even when systems are known to suboptimal operation, the presence of faults may be very difficult to manually localize and identify, making it a costly task for human operators who only act when indoor environmental conditions are not met. This lack of timely intervention raises the need for developing automated fault detection and diagnosis methods and technologies that assist the building operator.

Different fault detection and diagnosis (FDD) methodologies have been developed for HVAC systems, mostly based on expert knowledge to help identifying the faulty condition and its source [1]. However, a new trend in FDD is that of using models of the HVAC systems providing a base line for optimal operation, and supporting the detection of deviation from this optimum [2]. Model-based methods, offer the advantage of an increased flexibility to adapt to

different and innovative HVAC systems.

The focus of this paper is on a model-based diagnostic solution that uses a **qualitative model** for the part of the HVAC system corresponding to the **Air Handling Unit (AHU)**. This solution is derived from a general first-principle Modelica model and exploits a general diagnosis algorithm that isolates and identifies faults that occur frequently and can cause significant loss of system performance in AHUs: passing heating- and cooling-coil valves, and stuck dampers. An application example using a heating coil model is presented and provisions are made for the extension to other components.

The paper is structured as follows: section 2 provides an intuitive introduction to model-based diagnosis (MBD); section 3 outlines model requirements for on-line diagnosis while section 4 presents the modelica models and its calibration. In section 5 an example of the complete tool chain is discussed and finally, sections 6 and 7 provide concluding remarks and future work.

## 2 Model-Based Diagnosis: an intuitive introduction

Models used for designing and verifying control usually capture the nominal behaviour of the controlled physical system but are less reliable when modelling behaviours related to faulty operation. In fact, model-based diagnosis is able to perform fault **localization** using only models that represent the intended behaviour of the system (OK models) [3]. However, fault **identification** requires modelling the possible relevant faulty behaviours, as well, which may also lead to a more focused localization [3]. Therefore, for each system component, a health variable is defined as the health status (failure mode) of that component. A system health assignment (or health mode) is the set of health assignments for all components in the system.

To each component OK or failure mode, the respective (mis)behaviour is captured by a model (e.g. a set of (differential) equations. For example, a passing

Figure 1 From model to diagnosis, the MBD chain

heating coil valve will have hot water flowing in the heating coil when the heating coil is supposed to be switched off, in which case the air heats up after passing over this heating coil. Hence, in this case, the control setting is heating coil valve closed, but with the fault, the valve is actually open.

Based on this, each system health assignment implies one behaviour model of the entire plant, which is obtained by aggregating the component (fault) models.

Model-based diagnosis is based on an explicit representation of the knowledge about the components and the information about the plant structure, which determines how the components interact with each other. Based on a library of generic component models and the representation of the plant topology, a system model (possibly covering both the nominal and faulty behaviours) can be obtained automatically. This model is exploited by a generic diagnosis algorithm, which is not plant-specific and even not domain-specific (Figure 2). This way, diagnostics tailored to a specific plant require only the specification of the plant structure and component models; they are generated automatically instead of being hand-tailored. For the purposes of this research work, a plant model consisting of component models was built manually and then fed to the diagnostics tool that produces the diagnostics system automatically. However, steps have been taken to automate the full process by parsing the modelica file. This parsing can be done as long as certain naming convention is in place.

### 3 From Model to On-line Diagnosis

In this section, we present a complete workflow and

Figure 2 Generating Diagnostic Systems

system modules required to build a diagnostic solution for a class of plants (AHU) and to deploy it for a single plant and run it on-line, which is illustrated in Figure 1. Here, we give only an overview of the steps and modules, the most important ones being discussed in more detail in the following sections.

- **Producing the general solution** involves:
  - the production of a library of Modelica models (section 4) and;
  - its transformation into a qualitative diagnostic model library (top row Figure 1).
- **Producing an application system** based on the general solution, requires
  - The configuration and calibration of a Modelica model of the correct behaviour (named OK model and explained in section 4);
  - the composition of the diagnostic model based on the diagnostic library and the component structure of the plant, which can be extracted from this Modelica system model. This composition step is part of the functionality of the tool used in this work, *Raz'r* (from

[OCCM](#) Software GmbH). The extraction of the component structure from Modelica has not yet been realized, but is expected to be straightforward, given that the models have been developed following certain requirements, which are stated in section 3.1.

- For **on-line diagnosis**,
  - qualitative deviations are generated by computing the difference between the real data (currently for steady state only) and the predictions generated by the OK model of the plant (implemented in Modelica), and determining qualitative deviations based on given thresholds. A steady state filter is used to extract steady state data from the real operation data. The resulting qualitative deviations of dependent variables (and zero deviations for the exogenous variables) are processed by
  - the runtime diagnosis engine, which is produced by the code generator from the *Raz'r* module by compiling the consistency-based diagnosis algorithm and the diagnostic plant model into very compact C-code. The output is the set of all mode assignments containing minimal combinations of component faults that are consistent with the abstract observations [4].

### 3.1 Requirements on Modelling for Model-Based Diagnosis

In order to support the model-based diagnosis approach as previously outlined, the diagnosis models and, hence, also the numerical models to generate them from have to satisfy particular requirements:

- Strictly **component-oriented** modelling: the library has to be organized around the component types (with models that can be parameterized) that constitute the plant and that are units subject to diagnosis, e.g. heat exchangers, mass exchanger, mass movers, etc.
- **Fault models** should be represented (perhaps with a parameter characterizing the fault, such as the opening of a passing valve)
- The plant model has to be configured strictly according to the **real physical interconnections** in the plant. It must not include computational artefacts that link certain variables that are not really interacting directly via a physical connection. This includes using the concept of connectors in Modelica to reflect the channels of physical interactions between components (rather than connections via single variables as, for instance, in Matlab/Simulink).

The models in the library have to be formulated in a **context-independent manner** and must not rely on implicit assumptions about the presence and correct functioning of other components, even though they may exist in most standard configurations. This is relevant for two reasons: it enables the re-use of the component models for different plants, and it is a precondition for the adequacy of the models in fault situations.

## 4 Modelling a Simple Heating Coil

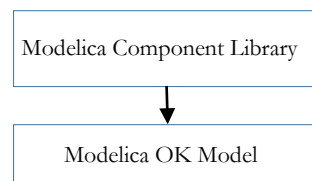

Figure 3. MBD first steps, model development and calibration

### 4.1 Model Development

Model development was driven by the specific application needs as specified in the previous section. These needs also encompass matching of the type of information interchanged between elements, reusability of the models, best use of manufacturer's data for setting up models and ease of use.

Ease of use and best use of manufacturer's data are closely related since the manufacturer's data is the first source of information a model developer will have in hand. In this regard, the developed model is such that this data is input into the parameters of the models corresponding this way to a first calibration step based on the manufacturer provided operation point. Table 1 shows the parameters, from the manufacturer's data, to be provided to the heating coil model.

Table 1. Manufacturer's datasheet operation point values needed as parameters for model setup

Heating Coil	air input temperature
	air output temperature
	air mass flow rate
	water input temperature
	water output temperature
	water mass flow rate

The heating coil model calculates the outlet steady-state conditions in both, water and air sides, using equations derived from the conservation of energy and mass principles and the definition of effectiveness in the classical eff-NTU method which given by equations (1), (2) and (3) [5]:

$$Q = C_a \cdot (T_{ao} - T_{ai}) \quad (1)$$

$$Q = C_w \cdot (T_{wi} - T_{wo}) \quad (2)$$

$$Q = \text{eff} \cdot \min(C_a, C_w) \cdot (T_{wi} - T_{ai}) \quad (3)$$

The effectiveness  $\text{eff}$  depends on the coil configuration (parallel flow, counter flow, or cross flow with both streams unmixed) [6]. The full modelica code is out of the scope of this paper but a snippet of the three main equations (1), (2), and (3) is shown below to illustrate the match between equation formulation and modelica code development:

```
Qflow = Cflow_a*(To_a - Ti_a);
Qflow = Cflow_w*(Ti_w - To_w);
Qflow=eff*min(Cflow_a,Cflow_w)*(Ti_w-
Ti_a);
```

For the heating-coil component, there are inputs and outputs for flow of air through the ducting, and flow of hot water through the heating coil. Hence, mass- and energy-balance equations must be defined for the airflow and water-flow. The imposition of energy- and mass- balance provides the remainder of the Modelica model equations.

## 4.2 Calibration

The calibration methodology uses real operation data obtained from the facility's building management system (BMS). For the calibration procedure, instead of trying to adjust each of the component's parameters, the approach used is by assuming all the calibration can be done with the valve model explained below in this section.

In the heating coil, the air outlet temperature is controlled by water mass flow rate using valves. A control signal determines the valve's position.

Real valves have no linear behaviour but they may present non-linear behaviour and even hysteresis. To model the valve's hysteresis, several options can be followed, e.g. using on-off hysteresis, linear hysteresis and non-linear hysteresis. For the purposes of this research work, a hysteresis as shown in Figure 4 was chosen since it produced a good trade-off between accuracy and simplicity. The chosen hysteresis model will still be a good representation of the real operation of the valve while it does not add important calculation burden to the model.

There are three parameters to calibrate. ' $mflowMAX$ ' is the water mass flow rate when the control signal is equal to 1 (maximum opening position),  $centHys$  and  $delta$  characterise the hysteresis' curve and the on/off points.

The real data has to be carefully observed to find maximum opening points and then the  $mflowMAX$  value is fixed in order to decrease the difference between real data and model results of the controlled variable in those points (temperature and/or humidity ratio).

Figure 4 Valve hysteresis function

To determine  $centHys$  and  $delta$ , the employed strategy was to find sharp changes in controlled variable (output air temperature). When the controlled variable has a sharp raise, the control signal coincides with a value equal to  $centHys + delta$ ; controlled variable has a sharp decrease, the control signal coincides with the value equal to  $centHys - delta$ .

Pre and post calibration results can be seen in Figure 5 and Figure 6.

In Table 2 we show calibration accuracy based on error metrics such as root mean square error (RMSE), coefficient of variation of the RMSE (CV-RMSE), mean bias error (MBE) and, normalised MBE (NMBE).

Table 2. Calibration Results

Heating Coil	RMSE (K)	CV RMSE	MBE (K)	NMBE
Pre-Calibration	1.57	0.52	-0.76	-0.26
Pos-Calibration	0.54	0.18	-0.07	-0.02

## 5 Qualitative Diagnostic Models

Figure 7 From numerical model to qualitative models

Figure 5 **non-calibrated** simulated (model) vs. measured (real) output air temperature for the heating coil model.

Figure 6 calibrated simulated (model) vs. measured (real) output air temperature for the **heating coil** model.

Creating a diagnostic library, based on the Modelica library, requires its transformation into a diagnostic model library. Figure 7 illustrates these steps.

The models used in our diagnostic approach are stated in relative, rather than absolute terms: they capture the deviation of variable values from the respective under nominal behaviour.

Following [7], [8]: the qualitative deviation of a variable  $x$  is defined as:

$$\Delta x := \text{sign}(x_{\text{act}} - x_{\text{nom}}) \quad (4)$$

Equation (4), captures whether an actual (observed, assumed, or inferred) value is greater, less or equal to the nominal value. The latter is the value to be expected under nominal behaviour, technically: the value implied by the model in which all components are in OK mode.

Qualitative deviation models can be obtained from standard models stated in terms of (differential) equations by canonical transformations, such as equations (5) and (6). We use  $\oplus$ ,  $\ominus$  and  $\otimes$ , to denote addition, subtraction and multiplication on signs.

$$a + b = c \Rightarrow \Delta a \oplus \Delta b = \Delta c \quad (5)$$

$$a * b = c \Rightarrow (a_{\text{act}} \otimes \Delta b) \oplus (b_{\text{act}} \otimes \Delta a) \ominus (\Delta a \otimes \Delta b) = \Delta c \quad (6)$$

It is important to note that these equations do not contain and require values for the reference values  $x_{\text{nom}}$  and, hence, can be applied to different plants and under distinct operating modes. The qualitative deviation models, obtained from the Modelica models, reflect current modelling assumptions, (steady state, and no deviation in airflow) and become very compact due to their qualitative nature and because constants can be dropped and just replaced by their signs. Internally, this model is automatically transformed into an efficient data structure representing finite relation.

In the following, we illustrate how this transformation can be done by manipulating the equations. According to energy balance equations (equations (1), (2) and, (3)), and assuming no losses, the energy balance in equation (7) can be reformulated in terms of deviations ( $\Delta$ ) as in equation (8).

Assuming that the air flow and the water temperature (drop) are positive and not deviating and replacing the capacity flow by the mass flow  $m_{\text{flow}_w}$  (which differ only by a constant factor), we obtain equation (9) which applies to all modes of the coil.

$$0 = C_a * (T_{ao} - T_{ai}) - C_w * (T_{wi} - T_{wo}) \quad (7)$$

$$0 = \Delta (C_a * (T_{ai} - T_{ao})) \oplus \Delta (C_w * (T_{wi} - T_{wo})) \quad (8)$$

$$0 = \Delta T_{ai} \ominus \Delta T_{ao} \oplus \Delta m_{\text{flow}_w} \quad (9)$$

Following equation (4), each of the variables used for diagnostics (equation (9)) can have a deviation of the measured value from the simulated one as follows:

- positively ('+'), when the actual (measured, predicted, or assumed) value is above the simulated plus a threshold;
- negatively ('-'), when the actual value is below the simulated minus a threshold;
- or not deviate ('0'), when the actual value is within the simulated value plus/minus the threshold.

Table 3 depicts the resulting relation on the three deviation variables, i.e. all solution tuples of equation (9). For instance, the first three rows of the table indicate the intuitive fact that, if the mass flow shows no deviation, a deviation of the incoming air temperature

will simply be propagated to the output air temperature.

On the other hand, a positive deviation of the output air temperature in combination with no deviation in the input air temperature, is only consistent with a positive deviation in the mass flow rate of the water (last-but-one row). From the diagnostic perspective, this reveals a fault in the coil (e.g. a passing valve), because a correct coil will not produce a deviating water flow. A valve stuck closed may lead to a negative deviation “-”, if the command Cmd to the valve is “open” (to some non-zero position, “+”). If the control commands the valve to be shut, anyway, a stuck-closed valve would cause no deviation in the water flow. This is captured by the model fragment in Table 5, which actually, is the complete fault model. Table 4 and Table 5 show the models of the OK mode and the passing valve, respectively. The table expresses that this mode may coincide with the nominal behaviour for a certain range of opening commands, but deviate positively for smaller valve positions.

With respect to their use for diagnosis, tables 4 – 6 jointly with table 3 capture which tuples of temperature and water flow deviations are consistent with which behaviour modes. Note that this does not require that the deviations can be observed directly. They may also be **predicted** by the system model based on observations for a particular system health assignment.

Bear in mind that a qualitative representation of one mode doesn’t exclude that any other mode can be reached with the same combination of inputs/outputs.

## 5.1 Runtime Deviation Generation

Figure 8 Generating Deviations

At runtime, the system will calculate deviations (Figure 8) by following the steps:

- Read each data vector corresponding to the sensor and actuator signals;
- Extract the exogenous variables including (external temperature, damper, and valve commands);
- Provide the exogenous variable values to the Modelica model of nominal behaviour, compare the values predicted by this model with the actual sensor data, and compute the deviations. In the current

Table 3. Relation on temperature deviations and water flow deviation

0	0
+	-

Table 6 Qualitative representation of the passing valve mode

Cmd	$\Delta m_{flow_w}$
0	+
+	0
+	+

solution, this is simply done by using a threshold (which can be different for different variables).

For the example with the heating coil documented here, a threshold of 2°C was chosen in order to produce deviations in the domain of signs (+, -, 0). In future solutions, different orders of magnitudes of the deviations could be generated by the abstraction module, which can take arbitrary sets of interval boundaries as an input.

For the example with the heating coil, Table 7 shows both the sensor data and the predicted values, highlighting the temperature before and after the heating coil. Using the 2°C threshold, the inflow air temperature is determined as nominal, while the outflow air temperature is higher than expected. This triggers a diagnosis event.

## 5.2 Diagnosis Inference

Figure 9 From deviations and qualitative model to diagnosis

The computed deviation pattern (with a zero deviation of exogenous variables -input temperature, and valve commands-) forms the input to the diagnosis runtime system (Figure 9). The deviation patterns will be checked for consistency with the possible models. In the trivial example restricted to one component presented in Table 7, the input/output temperature deviations (0, +) match with only one row in Table 3 that holds for all behaviour modes, which fixes  $mflow_w$  to be positively deviating. This positive deviation is consistent with the valve passing mode (Table 6), but neither with the OK mode, nor the stuck closed mode. Note, that this result can actually be concluded without information about the command to the valve.

What is illustrated here for a single component, is actually applied to the space of **plant** models covered by the system health assignments, which may yield alternative diagnosis hypotheses and also such that correspond to multiple component faults.

Table 7 Deviations between sensor data and model data

## 6 Discussion

In this paper a tool chain from model development to fault detection in air handling units has been presented and discussed with an illustrative example of a heating coil. The development tool of choice for the model was Modelica since it provides all the necessary tools to comply with model requirement for model-based fault detection as shown in section 3.1.

One of the main advantages of the model-based approach is the adaptability to different plants and to changes in the same plant. A brief description of the steps involved in adapting the qualitative model based diagnosis is presented below.

- **Structural changes:** These changes will have to be reproduced in the model, which would need to be compiled and recalibrated. The diagnosis model structure is a 1:1 mapping of the model and as such only minor adaptation is needed. However, if the change involves variables considered for diagnosis, the variable mapping between model and diagnosis framework has to be modified and tested with new data sets.
- **Parameter changes:** recalibration of the models is in principle the only requirement. In the case these parameter changes impact the accuracy of the

model, the tolerances of the diagnosis framework might have to be adjusted.

- **Sensor changes:** similar consideration to the case of structural changes should be taken in the case of adding new sensors or modifying position of existing ones. In the case that existing sensors are to be replaced with new ones with different precision, the steps described in the parameter changes are to be followed.
- **Changes in control:** plant model and diagnosis framework is, in principle, not affected by changes in the control strategy.

This adaptability makes model-based diagnosis a viable approach to fault detection and diagnosis in air handling units.

Taking into account that heating ventilation and air conditioning systems are rarely critical systems, the benefits of FDD in the build environment are more economic and environmental rather than being a safety issue and that hourly fault detection and diagnosis frequencies are more than acceptable in building applications; there is little scope for extending the models to include dynamic behaviour at the moment. Although in early stage, there exist scope for modelica models to become the de-facto standard in energy modelling of building components as shown by the recently established International Energy Agency Annex 60. Within this context, one of the key issues for model use during operation (e.g. Model-Based FDD, Model-Predictive Control, etc.) is the development of calibrated models that represent in a cost-effective manner the expected normal behaviour of the systems. Focused on air handling units' components, an approach to tack such problem, which can be automated, has been presented in this research paper

## 7 Future Work

Next steps in this research are:

- Development and testing of models for other components of HVAC systems;
- Improve the calibration methodology by developing an automatic calibration procedure that could be implemented underpinned by machine learning.
- Comparison of the qualitative model-based diagnosis approach with others such APAR rules or quantitative diagnosis
- Deployment and testing in a range of real units operating in normal environments.

# Simulation for verification and validation of functional safety

Lars Mikelsons   Zhou Su  
Bosch Rexroth AG  
Rexrothstr. 3, 97816 Lohr am Main

## Abstract

Safety of machinery is the most critical issue in the design of mechatronic systems. The verification and validation procedure for functional safety of machinery is thoroughly discussed in ISO 13849-2. Following this procedure, the system behavior in case of a component failure has to be analyzed. Up to now this analysis bases on expert knowledge and real experiments. In this contribution a simulation based approach is presented. This approach has several advantages over the state-of-the-art. First, real experiments are more time consuming and costly than simulation. Moreover, according models can be used for further investigations like optimizing the sensor setup.

To enable failure simulation as a substitute of testing on real machinery for validation of functional safety, typical hydraulic failures are added to safety-related components of an in-house Modelica hydraulics library. This library is then used for the verification and validation of functional safety of a hydraulic test bench. Moreover, error propagation is considered.

*Keywords: functional safety; hydraulics; simulation; failure modeling*

## 1 Introduction

### 1.1 Motivation

Safety is of primary concern for all machine designers. The functional safety of a mechatronic system is assured by the correct execution of safety functions. Those parts of the complete system that are relevant for the execution of safety-functions are denoted as safety-related part of the control system (SRP/CS). ISO 13849 provides guidelines to assure safety of mechatronic systems. While ISO 13849-1 [1] concentrates on the design of the SRP/CS, ISO 13849-2 [2] focuses on the validation of functional safety. Thereby, the reliability of the execution of a safety function is evaluated by a discrete measure called performance level (PL). The determination of the PL of a safety

function requires the analysis of the system behavior in case of one or more component failures of the SRP/CS. The failures that need to be considered for that analysis are also standardized in ISO 13849. The PL is then used to verify that a mechatronic system is functional safe, by checking that the PL of the SRP/CS is greater or equal to the required performance level ( $PL_r$ ) of the system. Obviously, the  $PL_r$  has to be derived beforehand from a risk assessment.

It is obviously desirable, that the validation of a safety function can be done solely by analysis, using mainstream failure analysis techniques like Failure Mode and Effect Analysis (FMEA) [3] or Fault Tree Analysis (FTA). However, in most industrial applications, the SRP/CS of a safety function are too complex to analyze the system behavior by the engineers intuition. Hence, the result of these failure analysis techniques is seldom conclusive. Consequently, testing on the real system must be carried out in order to get a reliable result. For these tests usually a prototype of the SRP/CS has to be constructed, which is a time consuming and costly task. Furthermore, correct insertion of the desired component failure into the test setup is not only difficult, but can also damage the prototype, e.g. if the influence of contaminated oil is investigated. In some applications, testing on actual constructed systems might not even be possible, e.g. if the considered failure leads to an hazardous situation for the operator. This is the case in hydraulic applications, when the housing of a component breaks, because this leads to an eruption of the oil at high pressure. To overcome the same problems (costly and time consuming prototypes), years ago simulation was established as a development tool. The use of simulation for the verification and validation of requirements is visualized in the mechatronic V-Model (see figure 1). However, up to now the requirements were mostly functional requirements. To the author's knowledge there exists no methodology to use simulation for the verification and validation of functional safety with respect to ISO 13849. Consequently, there are no libraries available

Figure 1: The mechatronic V-Model

that have a suitable level of detail, i.e. libraries including failure models. Obviously, it is desirable to model components including failures in such a way that

- the failures can be attached to a model without a failure (the original model),
- modification of the original model does not require modifications of the failures,
- the different failures can be easily exchanged,
- new failures can be added.

According to the first requirement physical models are needed. The remaining requirements aim for an object oriented model. Thus, Modelica seems to be appropriate to set up such models.

In this contribution an in-house hydraulics library is extended by components with failures, where the failures are modeled according to the requirements mentioned before. On the basis of that library it is shown how simulation can support and ease the design of a functional safe system. Moreover, an approach for error propagation is presented. A hydraulic test bench, which is used for testing hydraulic components like valves, is used as an application example. To summarize, the major benefits of the methodology presented here are:

- Optimization the typical work flow of design with respect to functional safety of mechatronic systems [4], i.e. replacing conventional analysis techniques and tests on prototypes by failure-simulation.

- Automated identification of the safety-critical failures in the SRP/CS.
- Investigation of error propagation.
- Future: Possibility to determine whether a failure can be detected by the sensor arrangements in the SRP/CS.

## 1.2 State-of-the-art

The concept of functional safety is derived from a functional system representation. Thus, most approaches for computer aided design of functional safe systems use functional models. A functional model is a block diagram of the system under consideration, where the blocks represent functions of the model and the connections represent a flow of energy, material or signals. Functional models can be generated at very early design stages, but suffer from the fact that they are rather rough, e.g. they do not include any dynamics.

Using these functional models, a Functional Failure Identification and Propagation framework is proposed for the analysis of functional failure propagation in [5]. However, this approach differs significantly from the method shown here and suffers from two major drawbacks. First, the level of detail of functional models is very low. Thus, the value of the gathered information is limited. Moreover, a special syntax and semantics are developed, so that existing models can not be used or upgraded for safety considerations. The same holds the methods described in [6] and [7] since the authors also use functional models. It is noteworthy, that the approach presented by Deng is originally intended for the verification of general requirements and can hence also be used for the verification of functional safety.

Most functional model-based analysis approaches are supported by failure analysis techniques like FMEA or FTA. An approach for combining both is presented in [8]. The coupling is done using the Systems Modeling language (SysML), a general-purpose modeling language. This method allows for automatic computation of a FMEA from a functional model, but suffers from the drawbacks described above. The use of ModelicaML [9] could be a promising future direction of the work presented here.

Although most simulation-based safety analysis methods use functional models, examples of physical models used for safety investigation can be found. A simple hydraulic system including a 4/3 directional valve, a motor-pump group and a cylinder is modeled with the help of bond graphs in [10] for

Figure 3: Principle of the risk reduction by the safety function

$$DC_{avg} = \frac{\frac{DC_1}{MTTF_{d1}} + \frac{DC_2}{MTTF_{d2}} + \dots + \frac{DC_N}{MTTF_{dN}}}{\frac{1}{MTTF_{d1}} + \frac{1}{MTTF_{d2}} + \dots + \frac{1}{MTTF_{dN}}}, \quad (1)$$

where  $MTTF_d$  denotes the mean time to a dangerous failure. In the seventh step the PL of the designed SCR/CS is determined. The PL depends on

- the category of the PLC,
- the reliability of the SCR/CS ( $MTTF_d$ ),
- the diagnostic coverage ( $DC_{avg}$ ).

There exist different approaches to compute the  $MTTF_d$  of the SCR/CS from the  $MTTF_d$  of the single components, e.g. Parts-Count-Procedure [4]. Using the  $MTTF_d$ , the category chosen in the fourth step and  $DC_{avg}$  determined in the sixth step, the PL can be read from a table given in [4]. Afterwards, the robustness of the PLC with respect to situations, that are not considered in the first steps, is analyzed in the eighth step. For example, in a redundant controller design all channels could fail due to violation of the maximum admissible operating temperature. In such cases adequate measures are taken. In the ninth step the software for the controller is developed with respect to state-of-the-art techniques and processes. In the last step the results from the previous steps are verified and validated. During the verification it is checked whether the required performance level has been reached. Otherwise the SCR/CS has to be improved, e.g. with components with a longer life cycle or a higher category. The plausibility of all the mentioned reliability parameters ( $MTTF_d$ , PL, category, DC), must be validated, either by analysis or with the help of testing/simulation. The complete validation procedure can be summarized as follows:

1. validation of safety functions
2. validation of performance level which includes:
  - validation of category specifications
  - validation of  $MTTF_d$  and  $DC_{avg}$
  - Validation of measures against systematic failure
  - validation of safety-related software
3. validation of combination and integration of all SCR/CS

Theoretically, this verification and validation can be performed solely by analysis. However, due to the complexity of most control systems, testing or simulation must be carried out to support inconclusive failure analysis.

Besides the use of simulation for validation it is useful for some other tasks. In the sixth step dangerous failures are identified. Up to now this is done basing on a functional model and the engineers expertise. Due to typically big and complex systems this approach is time consuming and error prone. Hence, the use of simulation would not only speed up the design process, but also lead to more meaningful results.

### 3 Failure models in Modelica

The DC\_HydrauLib is a Modelica library for the simulation of hydraulic systems developed by Bosch Rexroth. It contains hydraulic components like pumps, cylinders and valves. In this contribution it is used to present a possible approach for failure modeling in Modelica. This approach respects the requirements stated in the introduction. Using the language features of Modelica these requirements can be satisfied in the following way: Each failure is implemented in a new model that extends from the nominal model. All these models are then collected in a wrapper model (via replaceable), which is denoted as the failure model. Modeling this way one failure model consists of multiple models including failures. During application the user can choose the failure, that should be investigated by a parameter. The failures are implemented according to the list from ISO 13849-2 containing typical hydraulic failures. This list is developed without consideration of modeling and simulation. Hence, each failure is described on the base of the actual component construction. Examples for failures of a switching valve are

- Change of switching times
- Non-Switching (sticking at the end or zero position) or incomplete switching (sticking at a random intermediate position)
- Spontaneous change of the initial switching position (without an input signal)
- Leakage
- Bursting of the valve housing or breakage of the moving component(s) as well as breakage/ fracture of the mounting or housing screws

However, the hydraulic library contains only models with a level of detail suited for system simulation. Thus, a translation into implementable descriptions fitting to the abstraction level of the existing hydraulic library is required first. While the translation for the first two failures is straight forward, different translations for the remaining failures are possible, e.g.

- Spontaneous change of the initial switching position (without an input signal): A white noise input signal replaces the control signal when the failure is triggered.
- Leakage: Internal leakage with user-specified leakage coefficient.
- Bursting of the valve housing or breakage of the moving component(s) as well as breakage/ fracture of the mounting or housing screws: External leakage with a (big) user-specified leakage coefficient.

A brief overview on a possible implementation of the failures is given below.

**Change of switching times** The switching behavior of a switching valve is modeled by a trapezoidal profile, that is parametrized by the switching times (on/off separately). In addition to the parameters and variables inherited from the base model, two new parameters,  $r_{on}$  and  $r_{off}$  are introduced, which are defined as

$$r_{on} = \frac{T'_{on}}{T_{on}} \quad (2)$$

$$r_{off} = \frac{T'_{off}}{T_{off}}, \quad (3)$$

where  $T$  and  $T'$  are the original and the erroneous switching time of the valve, respectively. In case of a failure the erroneous switching times are used in the calculation of the spool dynamics.

**Non-switching** This failure is split into two failures, non-switching and random sticking. Non-switching means that the valve cannot open or close upon the next opening or closing input signal. Thus, this failure does not take effect immediately at the moment the failure is triggered. However, at the moment the failure is triggered the current spool position is saved and from that moment on used for the flow rate calculation instead of the spool position calculated in the spool dynamics.

Random sticking, takes effect when the failure type is triggered, which means that the spool stays at the current position when the failure is activated at any random time. The sticking position can either be the two end positions or any intermediate position. This failure is very common in directional valves, when the spring holding the spool at the end position is broken. The implementation is very similar to the non-switching behavior.

**Spontaneous position change** This failure describes the situation when the valve becomes totally uncontrollable, most likely due to breakage of the spool. For this failure, a white noise generator producing filtered noise with a user-specified bandwidth is used as the input for the spool dynamics. Notice that this noise generator is not really random. Only different seeds generate different noise output.

**Leakage** Leakage is an unavoidable problem in the construction of hydraulic valves. Leakage between two hydraulic ports is modeled as a volume flow rate proportional to the pressure difference  $\Delta p$  between the two ports

$$q = c \cdot \Delta p \quad (4)$$

with  $c$  as the leakage coefficient. Here, one has to distinguish between internal and external leakage. Internal leakage takes place between the two hydraulic ports of a valve. In the example of a switching valve with two ports (A and B), oil might flow from port\_A to port\_B, even when the valve is fully closed. External leakage is leakage to the environment (modeled as a tank). This model can also be used to simulate the breaking of the housing or similar failures.

Looking at the failures it is clear that there should be some kind of triggering mechanism. In this work two different triggering mechanisms have been implemented. In the first case the failure is

Figure 4: Hydraulic test bench

triggered at a user specified time. In the second case the failure is triggered by the violation of the working conditions of the corresponding component, e.g. pressure limitation, temperature range or fluid contamination. In this contribution only one working condition (pressure limits) is implemented. According to the specifications of the DC\_HydrauLib, both ambient and fluid temperature are constant during one simulation run, so exceeding the temperature range cannot be modeled using that library (until now). Similarly, fluid quality is also a fixed property of a selected oil type, thus contamination of oil can also not be modeled. Though, the user can specify a maximal operating pressure. If this maximal pressure is exceeded the chosen failure is triggered.

## 4 Application Example

In this section a test bench for hydraulic valves is used to present possibilities of the usage of failure simulation during the design phase of a hydraulic system. A typical safety function of this test bench (emergency stop initiated by user), is thoroughly investigated by simulation on the SRP/CS that executes this safety function.

### 4.1 Test bench

The hydraulic test bench (Figure 4) is designed for the testing of directional valves. The test bench is manufactured by Bosch Rexroth and applied in the production line of a Rexroth plant. Typical valve characteristics of the test item (specimen in figure 4) like leakage, characteristics curves and switching times can be tested. To perform all tests required for a test item,

the test bench must be able to provide various pressure and volume flow rates. During the productive period of the test bench, a trained operator stands in front of the test table to mount the test item. A test can only be started when the safety door (protective safeguard in figure 4) is open. On the other hand this door can only be lowered when the test item is correctly mounted. The test results are automatically recorded by the control devices of the test bench. Thereby, the test results can be severely impaired by a malfunction of the test bench, especially by component failures in the motor-pump group and the test table. For example, internal leakage inside the test bench may lead to test results, that indicate too big leakage of the test item. Moreover, if one of the safety functions, which are measures against risks, cannot be carried out due to internal component failures, the consequence can be even more disastrous. Thus, each time before the test bench is started a checking routine has to be performed. To reduce this non-productive period, and at the same time ensure the correct functioning of safety functions like emergency stop and safe door locking, is one of the most challenging issues in the designing of hydraulic test benches.

### 4.2 Circuit example

The safety function to be investigated for the hydraulic test bench (emergency stop initiated by user), is activated by pressing the emergency button on the control panel, and executed by de-energizing all engaged valves. Notice that in the execution of this safety function only the relevant actuators, namely valves engaged in cutting off the pressure supply, are de-energized. The energy supplier (the electrical motor within the motor-pump group) is still working, because it might be employed in other crucial functions of the test bench.

Two functional blocks exist between the oil pressure supply and the test table, where the test item is mounted. The block directly below the base frame of test table is the measurement block, which contains mainly sensors for measuring and valves for channel selection. This measurement block is designed to carry out all important tests on the test item. Notwithstanding its importance in the correct functioning of the test bench, it is not safety-related, since it does not execute a safety function. Moreover, malfunction of this measurement block only results in the non-execution of the designed tests on the test item. No danger is caused by the loss or degradation of this function. So the measurement block is out of the investigation scope of this

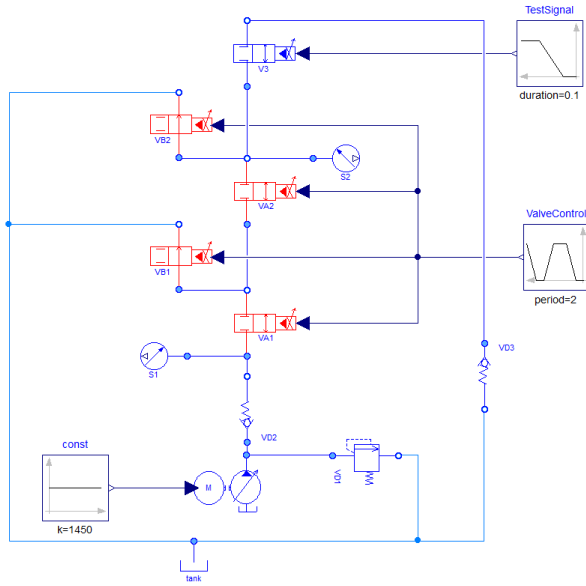

Figure 5: Simplified circuit diagram

contribution.

The other block is directly connected to the pressure supply. This block is designed to cut off the oil supply from the pump as fast as possible by de-energizing all engaged valves upon emergency. So this functional block is the active part to execute the safety function under consideration, and thus in the focus of the investigation in this contribution. The original system consists of several identical channels that can be connected to the test item. However, for the following investigations only one channel is considered for the reason of simplicity. Some additional simplifications lead to the circuit diagram in figure 5. Here, the red components (valve VA1, VB1, VA2 and VB2) are failure models. An explanation of the essential components is given in the following:

- VA1 and VA2: These 2/2 directional valves control the pressure supply of the test table. The valves have a switching time of 10ms and an internal induction sensor for spool monitoring (high DC value).
- VB1 and VB2: These 2/2 directional valves are opened in order to let the remaining oil between two valves flow back to the tank. The valves have a switching time of 10ms.
- VD1: This pressure relief valve limits the pressure in the circuit to 250bar.
- V3: This 2/2 switching valve imitates a test item.

Figure 6: Spool position of the valves in the reference simulation

### 4.3 Failure simulation

Before performing failure simulations, a failure-free simulation is first carried out as a reference behavior. During this reference simulation the safety function is triggered twice within five seconds. Thereby, the motor-pump group provides a constant volume flow rate of 40 l/min. Figure 6 shows the spool position  $y$  of all controlled valves (VA1, VB1, VA2, VB2 and V3). The safety function is triggered at 1s and 3s, respectively. Thus, at these times the valves VA1 and VA2 are de-energized (closed). Moreover, VB1 and VB2 also de-energized (opened) and thus let the residue oil flow back to the tank. Valve V3, which represents the test item, is controlled by a separate testing signal, and is not engaged in the execution of the safety function. It opens at 0.15 s and stays completely open throughout the whole simulation. The volume flow rate into the test item  $q_{V3}$  is the output variable since this variable is a measure for the danger of extruding oil. The volume flow rate into each major (VA1, VA2, VB1, VB2 and V3) is shown in figure 7. Valve VB1 and VB2 are auxiliary valves designed to let out residue flow when the main channel is suddenly cut off. Hence, the flow rate trough these valves is much smaller than the flow rate through VA1 and VA2.

The results of the reference simulation is used as the reference for all failure simulations performed in the following.

#### 4.3.1 Time triggered failures

In the first step described in Sec. 2 a risk assessment is performed. Here, simulation with failures injected

Figure 7: Volume flow rate at port\_A of all controlled valves in the reference simulation

Figure 8: Comparison of four failure simulations with the reference simulation

into only one of the safety-related components (VA1, VA2, VB1 and VB2) can be used in order to get better estimates of the consequences of component failures. In the sixth step it judged whether a failure leads to dangerous situation or not. Clearly, also here simulation can be used. However, here the use of simulation in the tenth step is shown, i.e. how to use simulation for validation. Therefore, the category of the SRP/CS is validated in the following. The chosen category for the system at hand is three ( $PL_r=d$ ). According to ISO 13849-2 this requires that a single failure does not lead to the loss of the safety function. Therefore, a Dymola script is used to simulate possible single failures. In figure 8 some typical results are presented. The trajec-

tories under investigation are the system output  $q_{V3}$ , which is the volume flow rate into the test item valve V3, and all measurable states, which are the displays of the two pressure sensors S1, S2 and the two internal sensors monitoring the spool position for valve VA1 and VA2. Sensor S1 is placed near the pump, and is used to monitor the pressure source of the whole system. Sensor S2 is placed at the inlet port of the test item valve V3, and is used to monitor the pressure provided to the test item.

It can be easily seen that the trajectories of  $q_{V3}$  and the two pressure sensor displays in the four test cases in figure 8 differ from the reference trajectories around 0.5s (valve VA1 and VA2 are opened). However, after the first triggering of the safety function at 1s,  $q_{V3}$  becomes almost identical to the reference trajectory for each test case. The same holds for all test cases not shown here. Thus, the safety function is successfully executed in all the four test cases and the safety function is not lost in case of a single failure.

Note that the validation of the category can thus be performed only based on simulation, which saves time and money (especially for more complex systems). Clearly, during the risk assessment also combinations of failures can be simulated.

#### 4.4 Error propagation

For the previous simulations, only time-triggered failures are considered. Another option for the failure triggering mechanism, in which a component failure is activated when a safety principle is violated, is considered in this section, for the investigation of error propagation.

Therefore, the failure-free pressure relief valve VD1 in figure 5, which is used for pressure limitation of the whole system, is replaced by an equivalent failure model. Note that the failure lists for pressure valves differs from the failure list for directional valves. The only investigated failure in this contribution is non-opening, which means that the valve cannot open completely (maximal 1%).

In the test case for error propagation the failure of the valve VD1 is triggered at 1s. Additionally, VA1 becomes uncontrollable (spontaneous spool movement), if the pressure at the inlet port exceeds the pressure limit of 400bar. The other valves (VA2, VB1 and VB2) exhibit a big external leakage (corresponds to the breaking of the housing), if the pressure limit (same as for VA1) is exceeded. Once again, a simulation of five seconds with two requests on the safety function is performed (denoted as Testcase 1 in the fig-

Figure 9: Results of the valve VA1 compared with the reference simulation

ures). In figure 9 the simulation results for valve VA1 are shown. It can be seen that the valve VA1 breaks down shortly (at 1.01s) after the failure of valve VD1 is triggered, because the pressure at the input port gets bigger than the pressure limit. From that time on the spool moves uncontrolled, which results in the presented volume flow. The valves VA2 and VB1 break down simultaneously shortly after the break-down of valve VA1 at 1.13s. This is, because the inlet ports of these two valves are connected to the same hydraulic port. The break-down of the valves VA2 and VB1 is modeled as big external leakage and hence these valves nearly act a tank for the rest of the simulation. That behavior explains the simulation results of the valve V3 (shown in figure 10). It can be seen that the volume flow after the failure of VA2 is much smaller than in the reference simulation. Note that the valve VB2 works properly, which indicates that the pressure at the end connector to the test item does not exceeds the maximum allowed pressure. This can also be confirmed by a look at the pressure sensor S2, which is even lower as in the reference simulation. This behavior occurs, because the valves VB1 and VA2, which are nearer to the pressure supply, break down earlier (and exhibit a big external leakage as explained before).

This example shows that it is possible to perform a model based estimation of the consequences of component failures, where even error propagation is considered.

Figure 10: Results of the valves V3 and VD1 compared with the reference simulation

## 5 Summary

In this contribution an approach for the use of simulation for the verification and validation of functional safety is presented. Therefore, a hydraulics library is extended by failure models. Thereby, the failure models depend on the original model in such a way, that the requirements stated in the introduction are satisfied. One possible use of these failure models is a risk assessment. The simulation of single failures lead to insight in the consequences of component failures. Here, also error propagation can be considered. Furthermore, the failure models can be used for the verification and validation step, e.g. the verification of the category as shown before.

In the future, optimization will be used for the identification of the worst case combination of failures. The results can either be used for the risk assessment or the identification of critical components. Moreover, the approach can be used in order to identify an optimal sensor setup. Therefore, on the one hand better sensor models have to be implemented and on the other hand algorithms for failure identification are required.

## Abstract

The formulation of the wheel-rail contact is a crucial issue in simulations considering the running dynamics of railway vehicles. Therefore a modeling environment that is dedicated to railway vehicle dynamics such as the new DLR RailwayDynamics Library relies on an efficient representation of the kinematics and forces or torques, respectively, that appear at the wheel-rail interface. A number of different formulations have been developed since the underlying rolling contact problem was firstly discussed in literature in 1876. The paper overviews these wheel-rail contact formulations and then presents the implemented variants in detail. The DLR RailwayDynamics Library is used to model and simulate the behavior of an experimental scaled M 1:5 running gear operating on the DLR roller rig. The simulations results are compared and validated with measurements. *Keywords: railway vehicles; wheel-rail contact; vehicle dynamics; multibody simulation*

## 1 Literature Review

### 1.1 Introduction

The wheel-rail interface is a constitutional element of railway vehicles. *Knothe* et al. [1] tell its three fundamental tasks each associated to a specific contact force component: load-bearing to the vertical force, guiding to the lateral force and traction to the longitudinal force. Although this appears to be very similar to the tire-road interface for automotive vehicles, the wheel-rail interface differs fundamentally due to wheel-rail geometry and the different material behavior of both contact partners which are made of steel.

The contact between wheel and rail in normal

Figure 1: Exemplary contact patch between wheel and rail and a qualitative surface plot of the associated normal stress distribution

direction is very stiff. The deformations of the contact partners add up to 1/10 or 2/10 mm, the contact area has an approximate size of 1 to 2 cm<sup>2</sup> although the usual transmitted vertical loads are very high, i.e. in the order of magnitude of 10 tons. Fig. 1 gives an impression of the size of the contact patch and the normal stresses here presented with a maximum of roughly 700 N/mm<sup>2</sup>.

In the tangential direction the contact behavior is ruled by friction. Therefore it depends on the normal contact conditions with friction coefficients between 0.1 and 0.4 and exhibits non-linear behavior and saturation.

This general specification already exposes the complexity of the wheel-rail contact problem which is also demonstrated by Fig. 2. There, the contours visualize the normal stress distribution as it is already given by the surface plot in Fig. 1. The arrows represent the tangential stress vectors and the circles indicate the points where the wheel surface slips along the rail surface since adhesion

Figure 2: Exemplary contact stresses and the associated slip region evaluated according to Kalker's non-elliptical rolling contact theory [2]

is depleted locally.

The fundamental normal and tangential contact properties motivate the use of conical wheel profiles so that the normal contact does not only carry vertical loads but as well contributes to the lateral guiding task. The additional consideration of undesired profile changes due to wear led to the evolution of specific wheel and rail profiles as they are shown in Fig. 3, see [3] for a more elaborate discussion on the significance of the profile geometry. It is obvious that such profile design introduces another complexity into the formulation of a wheel-rail contact model due to the geometry. For example, the shape of the outer stress field boundary in Fig. 2, usually denoted as non-elliptical, is a particular result introduced by the non-linear profile geometry.

## 1.2 Basic Modeling Issues

The goal of the modeling presented in this paper is to provide the capability of simulating the running dynamics of railway vehicles. Hence, it is important that the resultant forces that dominate the motion of the railway vehicle and are to be computed very often during one simulation job, are evaluated in reasonable accuracy and with low computational burden. However, it is not intended to give detailed and high accuracy information on the contact stress distribution as shown Fig. 2 and as it is required in order to examine e.g. rolling contact fatigue.

It is therefore a usual approach to review the

Figure 3: Terminology and characteristics of wheel and rail profile

wheel-rail contact problem looking for reasonable assumptions that simplify the modeling and reduce the computational effort. Tab. 1 gives an overview on widespread assumptions which may be applied according to the specific analysis goals at hand.

The separation assumption for example allows for introducing a virtual contact point where the resultant forces and torques acting on the wheel are assumed to be attached in order to simulate running dynamics. However the magnitude of the forces and torques are evaluated considering the contact problem separately.

Presuming identical materials for wheel and rail, the separation assumption together with the half-space approximation makes it possible to evaluate the normal contact first and independently and then derive the tangential stress quantities on top of it [1, Sec. 3.3.2].

Combining these two main simplification ideas with the discussion in Sec. 1.1 facilitates the formulation of the wheel-rail rolling contact problem by subdividing it into the following three subtasks that may be solved subsequently: the geometrical problem, the normal contact problem and the tangential contact problem.

A basic modeling aspect that is related to the multibody representation of the wheel-rail contact is the distinction drawn between rigid and elastic contact. In multibody theory the latter is equivalent to the description of the normal wheel-rail contact as a force law, while the ideal rigid contact leads to the concept of a kinematical constraint, so

Separation assumption	The deformations of the contacting bodies do not influence their overall motion so that wheel and rail may be assumed to be rigid bodies. Structural and contact mechanics may be considered independently from each other.
Linearity	The deformation fields are geometrically linear.
Half-space assumption	The contact area is very small compared to the characteristic dimensions of the related bodies in contact.
Ideal material	The material is linear-elastic, homogeneous and isotropic.
Identical material	Wheel and rail consist of identical materials.
Steady state assumption	The running velocity is small compared to the wave propagation within the material, so that quasi-static conditions are valid with respect to the contact problem.
Hertz assumption	The geometry of the contacting surfaces may be approximated as elliptic paraboloids so that the contact patch turns out to be a plain ellipse.
Dry Coloumb friction	Only dry friction is considered. The friction coefficient is constant and valid for adhesion as well as for sliding.

Table 1: Overview on assumptions frequently exploited for wheel-rail contact modeling, cp. [1, Ch. 3]

that the equations of motion form a differential-algebraic system [4]. The rigid contact requires a sophisticated preprocessing to guarantee the differentiability of the constraint equation and avoid artificial contact point jumps [5]. However, it is assumed to need less computational effort for time integration compared to the elastic contact that introduces very high stiffnesses into the equations of motion, but provides a more general applicability [6].

In the discussion so far it is assumed that the contact between wheel and rail forms one continuous contact area that may be idealized by one single contact point, which in fact is the dominant standard case. However specific configurations such as switch crossing or light urban and metro railway vehicles in sharp curves exist where multiple, non-connected contact areas between wheel and rail surface occur. These configurations require the consideration of multiple contact points, see e.g. [7] or [4].

### 1.3 The Normal Contact Problem

The basis for the highly accurate non-elliptical contact description e.g. shown in Fig. 2 has been set by *Kalker* [8] who implemented the program *Contact* that became a reference for railway contact problems. *Contact* fully accounts for the profile geometry of wheel and rail so that the simplification of the Hertz assumption from Tab. 1 is not employed. However, the half-space assumption is exploited to evaluate the stress and deforma-

tion field numerically. *Contact* is mainly applied for verification purposes in offline calculations. In addition, the same methodology has been used for detailed research about the influence of structural dynamics of wheel and rail on the vehicle-track interaction [2]. However for industrial applications, the accurate consideration of the non-elliptical contact requires too many computational resources, see e.g. [9] for optional approximations.

A very frequently used normal contact model in railway dynamics analysis is the *elliptical contact*. Here, the deviation of the contacting surfaces of wheel and rail from the ideal ellipsoidal shape is neglected and the contact stresses and deformations may be evaluated analytically according to the Hertz theory, see e.g. [10, Sec. 4.II.A].

For the sake of completeness the *Finite Element Method* shall be mentioned as a very general way to evaluate contact problems that does not rely on any of the mentioned simplifications in Tab. 1. Effects such as surface hardening, material flows or damage mechanism can be taken into account, see e.g. [11].

### 1.4 The Tangential Contact Problem

As soon as a relative motion, the so-called slip, between the contact point on the wheel and its counterpart on the rail occurs, tangential forces are transmitted. The program *Contact* is a widespread accepted reference to solve as well this tangential contact problem.

However in order to facilitate vehicle simu-

lations, *Kalker* proposed a simplified theory of rolling contact based on discretized ellipses and provided the *Fastsim* [12] algorithm that nevertheless takes traction and saturation into account.

For vanishing slip, if e.g. only very small traction forces are given, the linearized theory of *Kalker* [8, Sec. 2.2.2] is valid. Here, the tangential forces are a linear function of the slip.

A different class of tangential contact models try to get along with purely analytical considerations, as it is already done for the normal contact using the Hertz solution. However, these contact models require an assumption concerning the shape of the stick and slip region within the contact area. The basic idea originates from *Carter* [13], who showed that the tangential stress distribution of a cylindrical body rolling on a plane may be presented by two nested ellipses. The extension to three dimensions however relies on approximations that were proposed e.g. by *Vermeulen and Johnson* or by *Shen, Hedrick and Elkins* [13].

Following the same basic concept *Polach* [14] published a very efficient tangential contact solution in 1992 that coincides with *Kalker's* linear theory in the case of vanishing slip. In addition an extension is proposed for applications on the adhesion limit in which high traction forces are involved [15]. Besides the *Fastsim* algorithm the *Polach* model is wide-spread for multibody railway vehicle simulations today, see [16] for an assessment of various approaches.

## 1.5 Review Conclusions

The Modelica implementation of the wheel-rail contact is in particular supposed to support the development of new railway vehicle control concepts that are on the agenda of the DLR internal project Next Generation Train (NGT) [17]. For this purpose accuracy and computational effort have to be compromised. Therefore it has been decided to implement a rigid elliptical single point contact with tangential force law according to *Polach*.

## 2 Theory

### 2.1 Profile Geometry and Contact

In order to formulate the rigid contact, we look for an implicit constraint equation that defines the vertical wheel displacement  $z_w$  as a function of the lateral displacement  $y_w$ , the yaw angle  $\psi$  and the

Figure 4: Parametrization of the profile geometry.

roll angle  $\varphi$  of the wheel [5], i.e.

$$z_w + f(y_w, \varphi, \psi) = 0, \quad (1)$$

which is two times continuously differentiable [18].  $z_w$  and  $y_w$  are resolved with respect to the rail coordinate system R in Fig. 4, where the parametrization of the wheel profile  $F = F(s)$  and the rail profile  $G = G(y)$  is visualized as well.

The wheel surface  $S_w$  may be given in cylindrical coordinates of the wheel, i.e.  $S_w : (F(s), \tau, s)^T$ , or resolved with respect to R:

$$S_w : \mathbf{c}_S = \begin{pmatrix} 0 \\ y_w \\ z_w \end{pmatrix} + A(\varphi, \psi) \begin{pmatrix} F(s) \sin \tau \\ s \\ F(s) \cos \tau \end{pmatrix}, \quad (2)$$

where  $A(\varphi, \psi)$  represents the rotations around the  $x$ - and the  $z$ -axis of the wheel.

Those points on  $S_w$ , whose normal vectors to the surface are parallel to the  $(y, z)$ -plane of the rail define the curve  $C_w$  that is the projection of the wheel contour in the  $(y, z)$ -plane of the rail [19, Sec. 2.2]:

$$C_w : \mathbf{c}_C = \left\{ \mathbf{c}_S : \sin \tau(s) = -\tan \psi F(s), \right. \\ \left. \cos \tau(s) = \sqrt{1 - \sin^2 \tau(s)} \right\}. \quad (3)$$

We now specify the curve  $C_E$  to be independent from the vertical position of the wheel  $z_w$

$$C_E : \mathbf{c}_E = (x_E, y_E, z_E)^T := \mathbf{c}_C - (0, 0, z_w)^T, \quad (4)$$

which can be exploited to relate the wheel contour  $z_E = z_E(s; y_w, \varphi, \psi)$  to the associated rail profile

$G(y_E) = G(s; y_w, \varphi, \psi)$  as a function of the parameter  $s$ ,  $\underline{s} \leq s \leq \bar{s}$ .

Wheel and rail are in contact iff

$$z_w + \max_{\underline{s} \leq s \leq \bar{s}} \underbrace{(z_E - G)}_{\Delta(s; y_w, \varphi, \psi)} = 0. \quad (5)$$

The function  $\Delta(s; y_w, \varphi, \psi)$  in (5) is called the height function [5]. The value  $s^*$  that is assigned to the global maximum of  $\Delta$  specifies the contact point.

The direct application of (5) as constraint equation in multibody simulation for standard wheel-rail profiles such as S1002 and UIC60 does not make sense, since these profiles expose abrupt curvature changes and promote artificial jumps of the normal contact forces [4]. Therefore *Arnold et al.* [5] propose to use a regularization parameter  $\alpha > 0$  in the range  $10^{-5} \dots 5 \cdot 10^{-5}$  in the following way:

$$z_w + \text{smax}_s^{(\alpha)} \Delta(s; y_w, \varphi, \psi) = 0, \quad (6)$$

$$\text{smax}_s^{(\alpha)} \Delta := \alpha \ln \frac{\int_{\underline{s}}^{\bar{s}} \exp\left(\frac{\Delta(s; y_w, \varphi, \psi)}{\alpha}\right) ds}{\int_{\underline{s}}^{\bar{s}} ds}.$$

For small values of  $\alpha$  it can be shown that  $\text{smax}_s^{(\alpha)} \Delta \leq \max_s \Delta$ , i.e. (6) yields values of  $z_w$  that represent a small penetration  $\delta_{rw}$  of the wheel and rail bodies. The proposed values of  $\alpha$  are chosen in such a way that  $\delta_{rw}$  corresponds to the physical deformations of the contact partners, which could be evaluated e.g. according to the Hertzian theory. Therefore (6) is called the quasi-elastic contact model by *Arnold et al.*

The listing below shows that the geometrical problem is tackled by a Modelica function that takes  $y_w$ ,  $\varphi$ ,  $\psi$  and  $\alpha$  as inputs and mainly returns  $z_w$  in addition to quantities that are necessary for the tangential contact evaluation:

```
function findQuasiElasticContact
  "finds contact points on wheel and rail"
  import Modelica.Constants.pi;
  import SI = Modelica.SIunits;
  input SI.Position y_w
    "lateral displacement of wheel";
  input SI.Angle phi "roll angle [rad]";
  input SI.Angle psi "yaw angle [rad]";
  input SI.Radius r0 "nom. wheel radius";
  input Real alpha "smoothing parameter";
  output SI.Position z_w "vertical
    displacement of wheel center point";
  output SI.Position s0
    "lateral contact coordinate on wheel";
  output SI.Position v0
```

```
"lateral contact coordinate on rail";
output Real rho_x(final unit="m-1")
  "principal curvature at contact point
    in the plane normal to x-axis";
output Real rho_y(final unit="m-1")
  "principal curvature at contact point
    in the plane normal to y-axis";
output SI.Angle delta "contact angle";
```

The quantity  $s$  is an internal vector variable of this function which discretizes the wheel profile, e.g.  $s = \{-0.05, -0.0499, \dots, 0.05\}$ .

## 2.2 Kinematics

Consider the coordinate system in Fig. 5 in order to resolve the vectorial quantities in what follows. The  $\mathbf{e}_z$ -vector is normal to the wheel and the rail surface in the contact point C,  $\mathbf{e}_x$  is perpendicular to the wheel axis and heads in running direction.  $v_0$  is that component of the absolute velocity of the wheel center point  $\mathbf{v}_w$  that points in  $\mathbf{e}_x$ -direction.  $\boldsymbol{\omega}_w$  is the absolute angular velocity of the wheel that includes yaw, roll and the overturning motion  $\omega_0$  of the wheel.

The sliding velocity  $\mathbf{v}_s$  [20, Sec.2.6.2] in C follows from

$$\mathbf{v}_s = \mathbf{v}_w + \boldsymbol{\omega}_w \times \mathbf{r}_C \quad (7)$$

and is used together with  $\boldsymbol{\omega}_w$  to compose the slip vector  $\boldsymbol{\nu}$  with the longitudinal slip  $\nu_x$ , the lateral

Figure 5: Coordinate system associated to the plane through contact point C.

Figure 6: Icon layer of the contact model.

slip  $\nu_y$  and the spin  $\phi_z$ :

$$\boldsymbol{\nu} := \begin{pmatrix} \nu_x \\ \nu_y \\ \phi_z \end{pmatrix} = \frac{1}{v_0} \begin{pmatrix} v_{sx} \\ v_{sy} \\ \omega_{wz} \end{pmatrix} \quad (8)$$

Fig. 6 shows the the icon layer of the contact model with two multibody frame connectors from the Modelica Standard Library. The frames have to be connected to the center of the wheel and to the reference point on the rail which correspond to the points W and R in Fig. 4. The kinematical information of these two frames are required to evaluate (7) and (8).

The contact model does not have a state but represents a loop-closing element, which corresponds to the property that the wheel surface is constrained to be in touch with the rail surface. The constraint is formulated using the function from Sec. 2.1. As a result, the contact force in normal direction, i.e. normal to the plane through the point C according to Fig. 5 implicitly follows from the closed loop condition.

### 2.3 Hertzian Normal Contact

The pressure distribution  $p$  in the contact plane according to the Hertzian theory [21, (3.65)] is given by

$$p(x, y) = \frac{3f_n}{2\pi ab} \sqrt{1 - \frac{x^2}{a^2} - \frac{y^2}{b^2}}, \quad (9)$$

where  $f_n$  represents the absolute value of the normal force, while  $a$  and  $b$  denote the semi-axes of the contact ellipse and follow from

$$a = m \sqrt[3]{\frac{3(1 - \kappa^2)f_n}{E(A + B)}}, \quad b = n \sqrt[3]{\frac{3(1 - \kappa^2)f_n}{E(A + B)}}. \quad (10)$$

Beside Young's modulus  $E$  and Poisson's ratio  $\kappa$  that are assumed to be identical for wheel and rail, (10) uses auxiliary terms that are determined by

the curvature of the wheel  $\rho_{wx}$  and the rail  $\rho_{rx}$  measured in the plane normal to the  $x$ -axis and the wheel curvature in the plane normal to the  $y$ -axis  $\rho_{wy}$ :

$$A = \rho_{wx} + \rho_{rx}, \quad B = \rho_{wy}, \quad \vartheta = \arccos \frac{A - B}{A + B}.$$

$m$  and  $n$  are coefficients depending on elliptical integrals and specify the eccentricity of the contact ellipse. Tab. 2 is an extraction of [21, Tab. 3.4] to give an impression on their quantitative values.

$\vartheta$	$0^\circ$	$0.5^\circ$	$1^\circ$	$10^\circ$	$45^\circ$	$90^\circ$
m	$\infty$	61.4	36.89	6.604	1.926	1
n	0	0.1018	0.1314	0.3112	0.604	1

Table 2: Hertzian parameters for the contact ellipse.

In [5], it is proposed to introduce a weighed mean value of the curvatures in (10) that corresponds to (6), e.g. to consider the wheel curvature

$$\bar{\rho}_{wy} := \frac{\int_{\bar{s}} \rho_{wy}(s) \exp\left(\frac{\Delta}{\alpha}\right) ds}{\int_{\bar{s}} \exp\left(\frac{\Delta}{\alpha}\right) ds}. \quad (11)$$

Eq. (11) is implemented in the function presented in Sec. 2.1 as indicated by the output values given there.

### 2.4 Linear Tangential Contact

For vanishing slip *Kalker's*, i.e. for small values of  $\boldsymbol{\nu}$ , linear theory [8, Sec. 2.2.2] is valid so that the creep forces  $f_x$  and  $f_y$  in and the torque  $l_z$  normal to the  $xy$ -plane depend linearly on the slip  $\boldsymbol{\nu}$  under consideration of the shear modulus  $G$ :

$$\mathbf{f} = \begin{pmatrix} f_x \\ f_y \\ l_z \end{pmatrix} = \mathbf{C} \boldsymbol{\nu} \quad \text{with} \quad (12)$$

$$\mathbf{C} = -abG \begin{pmatrix} C_{11} & 0 & 0 \\ 0 & C_{22} & \sqrt{ab}C_{23} \\ 0 & -\sqrt{ab}C_{23} & abC_{33} \end{pmatrix}.$$

For the sake of demonstration Tab. 3 shows exemplary values of the coefficients that appear in (12).

### 2.5 Polach's Tangential Contact

According to *Polach* [14] the torque  $l_z$  in (12) is usually very small and can be neglected, while the

$b/a$	1	0.8	0.6	0.4	0.2	0.1
$C_{11}$	4.12	4.36	4.78	5.57	7.78	11.7
$C_{22}$	3.67	3.99	4.5	5.48	8.14	12.8
$C_{23}$	1.47	1.75	2.23	3.24	6.63	14.6
$C_{33}$	1.19	1.04	0.892	0.747	0.601	0.526

Table 3: Coefficients of *Kalker's* linear theory of rolling contact for  $\kappa = 0.25$  and  $a > b$  [8, E3].

influence of the spin  $\phi_z$  on the lateral creep force  $f_y$  may be of considerable importance. This is why his creep force law considers two lateral components:  $f_y^\circ$  denotes the creep force that originates from lateral slip and  $f_y^*$  is associated to the spin:

$$\mathbf{f} = \begin{pmatrix} f_x \\ f_y^\circ + f_y^* \\ 0 \end{pmatrix} \quad (13)$$

The tangential force in *Polach's* model is defined in the direction of the slip resultant  $\bar{\nu}$  taking the influence of the spin into account:

$$\bar{\nu} = \sqrt{\nu_x^2 + \bar{\nu}_y^2}, \quad (14)$$

$$\bar{\nu}_y = \begin{cases} \nu_y + a\phi_z & \forall \quad |\nu_y + a\phi_z| > |\nu_y| \\ \nu_y & \forall \quad |\nu_y + a\phi_z| \leq |\nu_y| \end{cases}.$$

In order to evaluate the resulting friction force  $\bar{f}$  it is postulated that the tangential stresses grow linearly with the distance from the leading edge until saturation is reached. Hence, the analytical integration of the assumed stress field over the contact patch leads to

$$\bar{f} = -\frac{2f_n\mu}{\pi} \left( \frac{k_a\varepsilon}{1 + (k_a\varepsilon)^2} + \arctan(k_s\varepsilon) \right), \quad (15)$$

where  $\mu$  denotes the friction coefficient,  $k_a$  and  $k_s$ ,  $k_s \leq k_a \leq 1$ , are reduction factors associated to the adhesion or the slip area, respectively. They have been introduced by *Polach* [15] in order to account for wet or polluted conditions.  $\varepsilon$  represents the gradient of the tangential stress in the area of adhesion at the leading edge of the contact patch and is related to the coefficients of *Kalker's* linear theory:

$$\varepsilon = \frac{G\pi ab C_{jj}}{4f_n\mu}, \quad C_{jj} = \sqrt{\frac{C_{11}^2\nu_x^2}{\nu_x^2 + \nu_y^2} + \frac{C_{22}^2\nu_y^2}{\nu_x^2 + \nu_y^2}}.$$

The subdivision of the  $\bar{f}$  into its two components corresponds to the slip partitions:

$$f_x = \bar{f} \frac{\nu_x}{\bar{\nu}}, \quad f_y^\circ = \bar{f} \frac{\nu_y}{\bar{\nu}}. \quad (16)$$

The remaining creep force component  $f_y^*$  is evaluated separately yielding

$$f_y^* = -\frac{\phi_z}{\bar{\nu}} \frac{9af_n\mu(1 + 6.3(1 - e^{-\frac{a}{b}}))}{16} \cdot \left[ \varepsilon^* \left( \frac{\delta^3}{-3} + \frac{\delta^2}{2} - \frac{1}{6} \right) + \frac{\sqrt{(1 - \delta^2)^3}}{3} \right], \quad (17)$$

where the tangential stress gradient due to spin  $\varepsilon^*$  and the abbreviation  $\delta$  are used:

$$\varepsilon^* = \frac{8Gb\sqrt{ab} k_a C_{23}}{3f_n\mu(1 + 6.3(1 - e^{-\frac{a}{b}}))} |\bar{\nu}_y|, \quad \delta = \frac{(\varepsilon^*)^2 - 1}{(\varepsilon^*)^2 + 1}.$$

For traction vehicles running on adhesion limit, the dependence of the friction coefficient on the slip velocity may be considered relating the maximum friction coefficient  $\mu_0$  to the limit friction coefficient  $\mu_\infty$  at infinite slip velocity introducing the parameter  $B$ :

$$\mu = \mu_0 \left[ \left( 1 - \frac{\mu_\infty}{\mu_0} \right) e^{-Bv_{sx}} + \frac{\mu_\infty}{\mu_0} \right]. \quad (18)$$

The above used constants  $k_a$ ,  $k_s$ ,  $\mu_0$ ,  $\mu_\infty$  and  $B$  are heuristic quantities that have been introduced to account for deviations from theory observed by measurements. Tab. 4 quotes *Polach* to give typical values.

conditions	$k_a$	$k_s$	$\mu_0$	$\mu_\infty$	$B[\text{s/m}]$
dry	1.00	0.40	0.55	0.22	0.60
wet	0.30	0.1	0.30	0.12	0.20

Table 4: Typical model parameters for dry and wet conditions of the real wheel-rail contact [15].

## 3 Application

### 3.1 Project Background

Fig. 7 shows an experimental running gear in scale 1:5 that operates on the DLR roller rig in Oberpfaffenhofen. Unlike usual wheel-set configurations this running gear has independently rotating wheels each driven by one wheel hub motor. Two opposite front wheels are mounted together on a cranked beam, the two rear wheels mounted on their carrier constitute the identical second wheel pair unit. Each wheel pair unit is connected to the central frame having one rotational degree of freedom around the vertical axis.

Figure 7: M 1:5 roller rig of DLR with experimental running gear for mechatronic guidance research.

That way the wheel pair units may perform independent yaw motions relative to the central frame. The central frame has two degrees of freedom with respect to the roller rig basis so it may move laterally and yaw.

The running gear has been designed in order to develop a new mechatronic guidance concept that allows for active steering. Significant wear, noise and weight reduction together with benefits that result from the low-floor configuration are goals that are on the agenda of the DLR internal project NGT [17].

### 3.2 Model Particularities

In parallel to the experimental environment a simulation model of the running gear on the test rig has been established in Modelica. The diagram layer of the Modelica model is visualized in Fig. 8 while an animation of the running gear operating on the roller rig is presented in Fig. 9. Both environments together are supposed to support the development of advanced control design concepts.

However the aim of this paper is rather the modeling and the validation of the wheel-rail contact that has been introduced in Sec. 2 and is instantiated four times in Fig. 8. The contact model named *Polach* uses two multibody frame connectors to be linked to the center of the wheel and to the center of the associated roller. Since the contact model represents a loop-closing element, the contact force in normal direction, implicitly follows from the closed loop condition. The tangential forces are evaluated as described in Sec. 2.5.

Fig. 10 shows the main part of the menu used to parametrize the contact model. The wheel profile here is not a standard one, but can here be represented by a true conical shape. The control of the running gear is defined in such a way that only a repactive region of the wheel tread is in contact. Therefore the parameter  $r\_wheel\_FrontView$  is set to  $1 \cdot 10^{12}$  or infinity, respectively in Fig. 10.

The discussion in Sec. 2.1 is implicitly restricted to the contact of wheels to prismatic rails, which is different here due the geometry of the rollers with

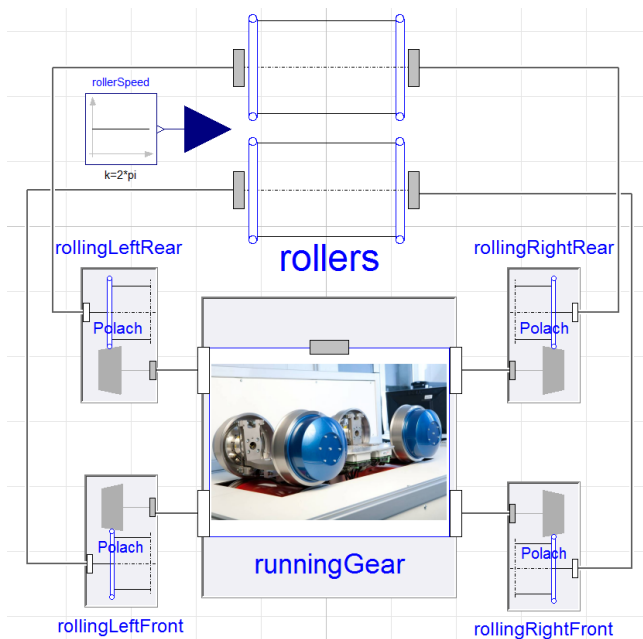

Figure 8: Diagram layer of the running gear model on the roller rig.

Figure 9: Animation of the running gear model.

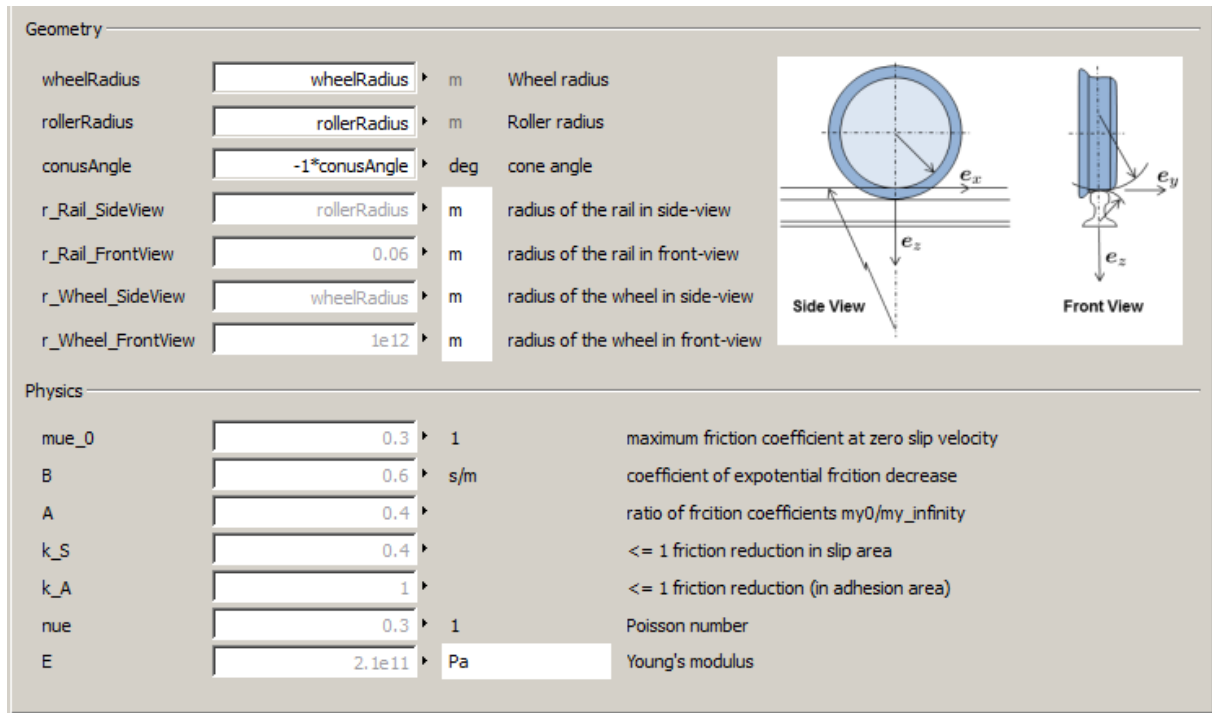

Figure 10: Parameter menu of the wheel-rail contact for conical wheel and curved roller profiles.

0.18 m radius. As soon as a wheel unit performs a yawing motion the two wheels leave the apexes of the associated rollers and slightly run downhill. This behavior is considered in the model but has been disregarded in Sec. 2, see [19, Sec. 2.2.2].

### 3.3 Results

A feature of the running gear are the force-torque sensors, that are assembled at the bearing of each wheel. Therefore the capability is given to compare simulation and measurement results with particular respect to the wheel-rail forces.

Fig. 11 to Fig. 13 show wheel-rail forces at the rear wheel on the right hand side. After the measurements have been low-pass filtered using a cut-off frequency of 20 Hz, the rotation frequencies of the roller and wheels still show up clearly, so that two narrow frequency bands of 0.2 Hz around these frequencies have been filtered out additionally. It is a current work field to eliminate or at least reduce the influence of the related disturbance sources.

The control of the running gear is set up in such a way that the running gear performs an artificial so-called hunting motion with 0.5 Hz frequency and a lateral amplitude of 8 mm. Whenever a conventional wheel-set is laterally excited e.g. by rail irregularities its dynamical response is a lateral

oscillation calling hunting. As long as the running velocity does not exceed a certain level, this motion is asymptotically stable. This is a desired dynamical property and a specific aspect of the wheel-rail profile design mentioned in Sec. 1.1. In addition hunting promotes wear not to be locally concentrated but distributed over a larger region of the wheel surface.

However independently rotating wheels do not show this passive behavior so that it has to be in-

Figure 11: Comparison of normal wheel-rail force,  $v_0 = 6$  m/s, 0.5 Hz hunting frequency.

Figure 12: Comparison of longitudinal wheel-rail force,  $v_0 = 6$  m/s, 0.5 Hz hunting frequency.

Figure 13: Comparison of lateral wheel-rail force,  $v_0 = 6$  m/s, 0.5 Hz hunting frequency.

troduced by feed-back control. The artificial hunting by control is the first proof a new mechatronic running gear concept has to stand, i.e. the mechatronic running gear has to perform at least as good as the conventional wheel-set design, before additional benefits could be approached.

Due to the hunting the normal wheel-rail force in Fig. 11 oscillates between 79 and 87 N. Measurements and simulation results correspond very good. The longitudinal forces in Fig. 12 show a long-wave deviation but are nevertheless rather close together. The values of the lateral forces in Fig. 13 are very small, which is actually intended by this specific running gear design. Therefore, the measurement tolerance of 0.25 N has to be considered when these results are assessed.

So far we are not able to measure the slip with sufficient accuracy. Therefore, the validation of the dependency of the forces on the slip is not possible today but will be tackled soon.

## 4 Conclusions and Outlook

From an intense literature review it has been concluded that a rigid elliptical single point contact with tangential force law according to *Polach* is expected to provide a well balanced compromise between accuracy and computational effort in order to establish a Modelica model of the wheel-rail contact.

Therefore the related theory has been summarized in Sec. 2. One additional refinement namely the quasi-elastic instead of the pure rigid contact

model has been introduced to guarantee a sufficient differentiability of the constraint equation.

This new Modelica wheel-rail contact is then applied to simulate the behavior of an experimental running gear on the scaled roller rig of DLR. The measured forces show a good agreement to the simulation results. A necessary advancement concerns the availability of slip measurements. Full scale applications with standard wheel-rail profiles will be modeled in the near future.

The new DLR RailwayDynamics Library, to which this wheel-rail contact model contributes a first cornerstone, is mainly intended to support the advanced observer and control design development and to facilitate multidisciplinary simulation tasks such as the interaction of running dynamics and drive train.

## Abstract

It is our predicament that we live in a finite world, and yet we behave as if it were infinite. Steady exponential material growth with no limits on resource consumption and population is the dominant conceptual model used by today's decision makers. This is an approximation of reality that is no longer accurate and started to break down. The World3 model, originally developed in the 1970s, includes many rather detailed aspects of human society and its interaction with a resource-limited planet. However, World3 is a rather complex model. Therefore it is valuable for pedagogical reasons to show how similar behavior can be also realized with models that are much simpler. This paper presents a series of world models, starting with very simple exponential growth and predator-prey systems, then investigates a minimal human-nature model, Handy, and ends with a brief account of the World3 model. For the first time, a simple human-nature interaction model is made available in Modelica that distinguishes between dynamics of Elite and Commoner social groups. It is shown that Handy can reproduce rather complex behavior with a very simple model structure, as compared to that of world models like World3.

*Keywords: Modelica, Simulation, Population Dynamics, World Models, Human-Nature Models.*

## 1 Introduction

Dynamic modeling can be applied to the human population and its interaction with the earth system. Certain types of such models are called World models.

Perhaps the earliest study indicating that human population would eventually reach limits to growth is that presented by Richard Malthus in 1798 in his famous work *An Essay on the Principle of Population* [4]. A catastrophe in the form of population collapse was considered as a possible consequence of uncontrolled growth that would hit the limits of food production causing massive famine.

A series of simulation models were developed mainly during the 1970's, with some later updates, aiming at understanding the complexity of the interactions between global societies and their physical environment, searching for the conditions that would lead to a collapse and possible measures that can avoid it. They formed the category of so-called World Models, typically of considerable generality and complexity, spanning several subsystems (demography, energy, economy, industry, agriculture, etc.) at varied levels of detail.

## 2 Growth without Limitations

In this first example, we shall show the dynamics of human populations in an idealized ecological system without limitations. We assume that a population contains  $P$  individuals. In general, the rate of change of the number of individuals is the difference between the population birth rate and its death rate:

$$\dot{P} = \text{birthrate} - \text{deathrate} \quad (1)$$

where  $\dot{P}$  means  $dP/dt$ , the rate of change of the population stock. It is natural to assume that the birth and death rates are proportional to the size of the population:

$$\begin{aligned} \text{birthrate} &= g \cdot P \\ \text{deathrate} &= d \cdot P \end{aligned} \quad (2)$$

where  $g$  is the growth (birth) factor and  $d$  the decrease (death) factor for the population. These factors can be assumed to be constant if the same amount of food per individual is available independent of the size of the population, and if no sudden lethal events (disease, war) affect the population massively. These assumptions are of course valid only for a reasonably limited size of the population, since food supply is never infinite in a closed system and epidemics, pandemics, and wars sometimes break out. Putting (1) and (2) together gives:

$$\dot{P} = (g - d) \cdot P \quad (3)$$

Solutions to this equation yield an exponentially increasing population if  $(g - d) > 0$  or an exponentially decreasing one if  $(g - d) < 0$ . We represent this equation in the model class `PopulationGrowth` below:

```
class PopulationGrowth
  parameter Real g = 0.04 "Growth factor";
  parameter Real d = 0.0005 "Death factor";
  Real P(start=10) "Pop. size, init 10";
equation
  der(P) = (g-d)*P;
end PopulationGrowth;
```

The model is simulated and the population size  $P$  is plotted below:

**Figure 1.** Exponential growth of a population with unlimited food supply.

As expected, Figure 1 shows an exponentially increasing population. We should, however, remember that exponential growth can never persist indefinitely in a closed system with a limited food supply.

## 3 A Predator-Prey Model with Limitations in Prey Animal Population

Now we will study a more interesting system consisting of interacting populations of predators and prey animals.

The simplest predator-prey model, the so-called Lotka-Volterra model [3], consists of two population stocks. We may think of predators as foxes and preys as rabbits.

The rabbit population of size  $R$  is assumed to have an unlimited food supply. Therefore equation (3) applies regarding the birth rate of the rabbit population, with a positive growth term  $g_r \cdot R$ , where  $g_r$  is the growth factor for rabbits.

On the other hand, the fox population of size  $F$  feeds on the rabbits. The rabbit death rate can be assumed to be proportional to the number of foxes due to increased hunting pressure, and to the number of rabbits due to the higher probability of success in hunting, giving a rabbit death rate due to foxes of  $d_{rf} \cdot F \cdot R$ , where  $d_{rf}$  is the death factor of rabbits due to foxes. Putting the birth and death rates together gives the total rabbit population change rate  $\dot{R}$  as defined by equation (4) below:

$$\dot{R} = g_r \cdot R - d_{rf} \cdot F \cdot R \quad (4)$$

The growth of the fox population of size  $F$  is proportional to the rate of rabbits consumed, i.e., those that die because they were hunted by foxes, which is the death rate term  $d_{rf} \cdot F \cdot R$  mentioned in the previous equation. The efficiency of growing foxes from rabbits is determined by the growth factor  $g_{fr}$ , giving a fox population growth rate term  $g_{fr} \cdot d_{rf} \cdot R \cdot F$ . The fox population also has an intrinsic death rate  $d_f \cdot F$  proportional to the size of the fox population by the fox death factor  $d_f$ . By combining these two terms, we obtain equation (5):

$$\dot{F} = g_{fr} \cdot d_{rf} \cdot R \cdot F - d_f \cdot F \quad (5)$$

where  $\dot{F}$  is the total change rate of the fox population.

We have created a Modelica [2][8] class below called `LotkaVolterra` that includes both equations (4) and (5) along with all the variables and constant proportionality factors. The two state variables  $R$  and  $F$  for the sizes of rabbit and fox populations are represented by the Modelica variables `rabbits` and `foxes`:

```

class LotkaVolterra
  parameter Real g_r = 0.04 "Natural
  growth rate for rabbits";
  parameter Real d_rf = 0.0005 "Death rate
  of rabbits due to foxes";
  parameter Real d_f = 0.09 "Natural
  deathrate for foxes";
  parameter Real g_fr = 0.1 "Efficiency
  in growing foxes from rabbits";
  Real rabbits(start=700) "Rabbits, (R)";
  Real foxes(start=10) "Foxes, (F)";
equation
  der(rabbits) = g_r*rabbits -
    d_rf*rabbits*foxes;
  der(foxes) = g_fr*d_rf*rabbits*foxes -
    d_f*foxes;
end LotkaVolterra;

```

The model is simulated, and the sizes of the rabbit and fox populations as a function of time are shown below (Figure 2):

**Figure 2.** Number rabbits—prey animals, and foxes—predators, as a function of time simulated from the PredatorPrey model.

The Lotka-Volterra model has a rather special property: the solution variables, i.e., the rabbit and fox population sizes, do not approach constant steady-state levels (unless they start at those equilibrium levels, which is rarely the case). Instead, they exhibit oscillatory equilibrium. The shape of these oscillations, very characteristic for Lotka-Volterra models, corresponds rather well to several experimental population studies of predators and prey animals. However, this does not prove these partly inductive model equations to be correct, only that they seem to have certain approximate physical significance.

## 4 A Minimal Human-Nature Dynamical Model with Economic Stratification

Simplified approaches to World models can exhibit interesting behavioral patterns while keeping model complexity low enough to enable intuitive comprehension. One such simplified model is *Handy* (Human and Nature Dynamical model) [9] developed jointly by researchers at the University of Maryland and the University of Minnesota<sup>1</sup>.

The *LotkaVolterra* model (Section 3) was the original inspiration behind *Handy*, which is not a world model in the typical sense, although, in principle, it can be applied to a homogenous world.

*Handy* has four differential equations describing the evolution of its state variables: Commoner population (*commoners*), Elite population (*elite*), regenerating natural resources (*nature*), and accumulated wealth (*wealth*). Human population plays a role analogous to that of predators, and *nature* plays the role of the resource preyed upon.

An interesting feature of *Handy* is that it introduces the accumulation of economic *wealth*, and divides the human population into rich and poor according to their unequal access to available wealth.

This new variable explains why human societies can undergo an irreversible collapse, while animal populations show cyclic changes (or reversible collapses).

Social inequality is not only explicitly considered but also plays a key role in the sustainability analyses of the model. This makes *Handy* the first model of its kind that studies the impacts of inequality on the fate of societies, a capability seldom found even in complex world models.

*Handy* establishes a useful general framework that allows carrying out “thought experiments” about societal collapse scenarios and the changes that might avoid them.

The model is a very strong simplification of the human-nature system, which results in many limitations. Despite its simplicity, such a model is easy to understand and offers a more intuitive grasp of underlying dynamical phenomena compared to more complex and less aggregated models.

We briefly introduce a much more advanced class of world model called *World3* in Section 5 of this paper. This model (the compiled version) features 41 state variables and 245 algebraic variables. It captures many

<sup>1</sup> The *Handy* model has been publicly available since 2010 in the form of unpublished reports and presentations, deposited on the web site of its authors:

[http://www.atmos.umd.edu/~ekalnay/#publications\\_based](http://www.atmos.umd.edu/~ekalnay/#publications_based).

aspects of the human system and ecology, and it has been calibrated against empirical data.

#### 4.1 Handy Model Equations, Description, and Modeled Societies

The Handy model divides the total population into two classes: Commoners and Elites, of population sizes `commoners` and `elite`, respectively. Population grows through birth rates `birthRComm` and `birthRElite`, which are constants. The population shrinks through death rates `deathRComm` and `deathRElite`, which are modeled as functions of `wealth`.

The state variables of the model are described in Table 1, additional variables in Table 2, and the parameters of the model in Table 3.

A single stock (variable), `nature` represents an amalgamation of nonrenewable and renewable resources, including “regenerating” resources such as forests, soils, and animal and fish stocks, etc.

The dynamics of the model are defined by the following four differential equations:

$$\begin{aligned} \text{commoners}' &= \text{birthRComm} \cdot \text{commoners} - \text{deathRComm} \cdot \text{commoners} \\ \text{elite}' &= \text{birthRElite} \cdot \text{elite} - \text{deathRElite} \cdot \text{elite} \\ \text{nature}' &= \text{natureRegen} \cdot \text{nature} \cdot (\text{natureCap} - \text{nature}) \\ &\quad - \text{depletFactor} \cdot \text{commoners} \cdot \text{nature} \\ \text{wealth}' &= \text{depletFactor} \cdot \text{commoners} \cdot \text{nature} \\ &\quad - \text{consRComm} - \text{consRElite} \end{aligned}$$

which in Modelica are expressed as:

```
der(commoners) = birthRComm*commoners -
deathRComm*commoners;
der(elite) = birthRElite*elite -
deathRElite*elite;
der(nature) =
natureRegen*nature*(natureCap-nature) -
depletFactor*commoners*nature;
der(wealth) =
depletFactor*commoners*nature - consRComm-
consRElite;
```

The equation for `nature` includes a regeneration term `natureRegen*nature*(natureCap-nature)` and a depletion term `depletFactor*commoners*nature` intended to also include degradation in nature caused by pollution.

The regeneration term is synthetic (i.e., not directly physical) following an s-shaped form<sup>2</sup> parameterized to resemble physically realistic results.

It exhibits exponential growth for low values of `nature` (because `natureCap-nature` is almost constant for small `nature`), reaches its maximum at `nature=natureCap/2`, and becomes small when `na-`

ture approaches `natureCap` (maximum size of `nature` in absence of depletion).

The depletion term includes a rate of depletion (pollution) per worker `depletFactor` making it proportional to both `nature` and `commoners` (labor). The economic activity of Elite is modeled to represent supervisory functions with no direct influence on the extraction of resources or the production of wealth. The underlying concept is that “only commoners produce.” Handy does not model the impacts of technological change, considering that technology through history has proven to produce both increases and decreases in resource use efficiency. Thus, a simplification is made assuming that these effects cancel each other out.

Accumulated Wealth (`wealth`) increases with production (`depletFactor*commoners*nature`) and decreases according to the consumption rates of the Elites and the Commoners, `consRComm` and `consRElite`, respectively.

**Table 1.** Main state variables of the Handy model.

Name	Description	Unit	Typical initial value(s)
commoners	Commoner population size	Number of people	100
elite	Elite population size	Number of people	0, 1, 25
nature	Nature's stock	EcoDollars	<code>natureCap</code> = 100
wealth	Accumulated wealth	EcoDollars	0

The additional variables of the model are described in Table 2. Two of these variables describe consumption. The consumption of the Commoners, `consRComm`, is given by a subsistence salary per capita `subsSal` times the working population. Elites earn a salary that is `ineqFactor` times larger than that of Commoners, intended to simulate class inequality, and is considered time-independent for any given scenario. This is reflected in the following equations:

$$\text{consRComm} = \min(1, \text{wealth} / \text{wealthMin}) \cdot \text{subsSal} \cdot \text{commoners}$$

$$\text{consRElite} = \min(1, \text{wealth} / \text{wealthMin}) \cdot \text{subsSal} \cdot \text{elite} \cdot \text{ineqFactor}$$

which in Modelica are expressed as:

```
consRComm = min(1, wealth/wealthMin) *
subsSal*commoners;
consRElite = min(1, wealth/wealthMin) *
subsSal*elite*ineqFactor;
```

Both consumption rates, `consRComm` and `consRElite`, are subject to a “famine” minimum threshold for accumulated wealth before famine, `wealthMin`. The consumption rates are linearly reduced down to zero by the `min()` terms in the above equations, when `wealth` falls below `wealthMin`.

The death rates of the Commoners and the Elite are defined by the following equations:

<sup>2</sup> This is the well-known “logistic equation” used in many domains of life sciences to represent exponential growth followed by smooth saturation.

$$\begin{aligned}
deathRComm &= deathRnormal + \max(0, 1 - consRComm \\
&\quad / (subsSal \cdot commoners)) \cdot (deathRfamine - deathRnormal) \\
deathRElite &= deathRnormal + \max(0, 1 - consRElite \\
&\quad / (subsSal \cdot elite)) \cdot (deathRfamine - deathRnormal)
\end{aligned}$$

The carrying capacity (`carryingCap`) of population, i.e., the population that can be sustained by the re-growth of nature, and its corresponding maximum carrying capacity (`carryingCapMax`), attainable under certain conditions, are defined by these equations:

$$\begin{aligned}
carryingCap &= natureRegen / depleteFactor \cdot \\
&\quad (natureCap - subsSal \cdot eta / depleteFactor)
\end{aligned}$$

$$carryingCapMax = natureRegen / (eta \cdot subsSal) \cdot (natureCap / 2)^2$$

The threshold for minimum wealth (`wealthMin`), the total population, and a dimensionless quotient `eta` used above are defined as follows:

$$\begin{aligned}
wealthMin &= consWorkerMin \cdot commoners + \\
&\quad ineqFactor \cdot consWorkerMin \cdot elite \\
eta &= (deathRfamine - birthRComm) / \\
&\quad (deathRfamine - deathRnormal)
\end{aligned}$$

$$totalPopulation = elite + commoners$$

**Table 2.** Additional variables of the Handy model for Human and Nature Dynamics.

Name	Description	Unit
deathRComm	Commoners' death rate	Number of people/year
deathRElite	Elites' death rate	Number of people/year
consRComm	Consumption rate of commoners	EcoDollars/year
consRElite	Consumption rate of Elites	EcoDollars/year
eta	Dimensionless quotient	
carryingCap	Carrying capacity (of the whole system)	Number of people
carryingCapMax	Maximum carrying capacity	Number of people
totalPopulation	Total population	Number of people

The parameters of the model are described in Table 3.

**Table 3.** Parameters of the Handy model for Human and Nature Dynamics.

Name	Description	Typical value(s)
deathRnormal	Healthy normal (minimum) death rate	0.01
deathRfamine	Famine (maximum) death rate	0.07
birthRComm	Commoner birth rate	0.03, or 0.065
birthRElite	Elite birth rate	0.03, or 0.02
subsSal	Subsistence salary per person	0.0005
consWorkerMin	Minimum required consumption per worker	0.005
natureRegen	Nature's regeneration rate	0.01

natureCap	Nature's carrying capacity	100
ineqFactor	Inequality factor between elite and commoners	1, 10, or 100
depletFactor	Depletion (production) factor	6.67E-6, or 6.35E-6, or 13E-6

There are three dimensions for quantities in the model: Population (either Commoners or Elites), in units of people, Nature or Wealth, in units of EcoDollars, and Time, in units of years. All other parameters and functions in the model carry units that are compatible with these dimensions.

All of the above definitions appear in the HandyBase Modelica model below, which is a partial model that is inherited by the following actual simulated models.

```

partial model HandyBase "Equations,
variables, and parameters for Handy"

end HandyBase;

```

## 4.2 Types of Societies, Simulation Methodology and Scenarios

Handy has been applied to three types of societies:

- *Egalitarian society*—with no elites, i.e., the elite population `elite = 0`. Scenario models `HandyEgal1` to `ModelEgal4`.
- *Equitable society*—with workers (commoners) and elites (non-workers), where both groups earn the same per person, i.e., `ineqFactor=1`. Scenario models `HandyEquit1` to `HandyEquit5`.
- *Unequal society*—with commoners and elites, where elites consume more per capita than commoners, i.e., `ineqFactor > 1`. Scenario models `HandyUnEq1` to `HandyUnEq4`.

Several scenarios will be studied for each kind of society. The default values for parameters and initial values for state variables used in these scenarios are those presented in Table 1 and Table 3.

The thought experiments are performed as simulations, the results of which are presented in Sections 4.3 and 4.5, respectively. Within each type of society, different scenarios are studied by varying the rate of depletion per worker called `depletFactor` (short for depletion factor).

For each type of society, an equilibrium state can be reached, in which all derivatives go to zero, and consequently, all the system's variables settle into a steady state.

Under that condition, the carrying capacity can be maximized if nature's regeneration rate is maximal. According to the equation for nature, the latter is satisfied when `nature=natureCap/2`. The depletion factor `depletFactor` is at the optimal level `depletFactorEq`, when it produces a steady state with a maximum sustainable population.

The scenarios below explore the consequences of different types of societies as they behave optimally or sub-optimally, determined by the depletion factor.

## 4.3 Simulation Scenarios of an Egalitarian Society

For this type of society, the optimal value for the depletion factor that maximizes the carrying capacity (`carryingCap`) is `depletFactorEq=6.67E-6` (derived analytically). Below is the `HandyEgalitarianBase` model that is being inherited by all `Egal` models.

```

partial model HandyEgalitarianBase
  "Egal - Scenarios with Egalitarian
  Society (No-Elite)"
  extends HandyBase;
  initial equation
    elite = 0; // For All "Egal" scenarios
    commoners = 100.0;
  end HandyEgalitarianBase;

```

*Scenario Model HandyEgal1: "Soft landing to Equilibrium"*

```

model HandyEgal1 "Scenario Egal1: Soft
Landing to Equilibrium"
  extends HandyEgalitarianBase;
  equation
    depletFactor = depletFactorEq;
  end HandyEgal1;

```

By making `depletFactor=depletFactorEq` the results in Figure 3 below are obtained:

```

plot({commoners_, elites_, nature_,
wealth_, carryingCap_, carryingCapMax_})

```

**Figure 3.** Soft landing to equilibrium, with optimal nature depletion factor. Simulation of HandyEgal1.

In this example, maximum nature regeneration can support a maximum sustainable depletion rate (pollution) and a steady maximum population (commonsers) equal to the carrying capacity (carryingCap).

*Scenario Model HandyEgal3: “Cycles of Prosperity and Collapse”*

In this scenario we increase the depletion intensity by selecting  $\text{depletFactor} = 4 * \text{depletFactorEq}$ .

```
model HandyEgal3 "Scenario Egal3: Cycles
  of Prosperity and Collapse"
  extends HandyEgalitarianBase;
  equation
    depletFactor = 4 * depletFactorEq;
  end HandyEgal3;
```

The results obtained are shown in Figure 4 below:

```
plot({commonsers_, elites_, nature_,
  wealth_, carryingCap_, carryingCapMax_})
```

**Figure 4.** Cycles of Prosperity and Collapse. Simulation of HandyEgal3.

The oscillatory mode exhibits “reversible collapses”. This scenario can be seen as belonging to a “limit cycle” for the values of the depletion factor. If  $\text{depletFactor}$  increases even further, the system changes into a different mode, one of “irreversible” collapse, with only one overshoot-and-collapse cycle. This is obtained in the scenario HandyEgal4.

*Additional Scenarios in an Egalitarian Type of Society*

There are also scenarios models HandyEgal2 “Oscillatory Approach to Equilibrium” and HandyEgal4 “Full

Collapse”, corresponding to  $\text{depletFactor} = 2.5 * \text{depletFactorEq}$  and  $\text{depletFactor} = 5.5 * \text{depletFactorEq}$ , respectively. The reader is encouraged to test these models.

#### 4.4 Simulation Scenarios of an Equitable Society—Workers and Non-Workers with Equal access to Wealth

In this society, Non-Workers and Workers have equal access to wealth, i.e.,  $\text{ineqFactor} = 1$ . The non-workers’ privilege is that they get access to wealth without having to work (in that sense, they are regarded as the Elites). The initial population of non-workers is  $\text{elite} = 25$ . As before, we look for an equilibrium situation where the depletion factor is set to its optimal value, which for this society is  $\text{depletFactor} = \text{depletFactorEq} = 8.33\text{E-}6$ . This produces the first scenario HandyEquit1 model shown further below, an adaptation of the HandyEquitableBase model which is inherited by all Equit scenario models.

```
partial model HandyEquitableBase
  "Equit Scenarios: Equitable society
  (with Workers and Non-Workers)"
  extends HandyBase(ineqFactor = 1,
    depletFactorEq = 0.00000833);
  initial equation
    commonsers = 100.0;
  end HandyEquitableBase;
```

*Scenario HandyEquit1: “Soft Landing to Optimal Equilibrium”*

```
model HandyEquit1
  "Equitable society Scenario Equit1: Soft
  Landing to Optimal Equilibrium"
  extends HandyEquitableBase;
  initial equation
    elite = 25;
  equation
    depletFactor = depletFactorEq;
  end HandyEquit1;
```

We simulate and plot:

```
plot({commonsers_, elites_, nature_,
  wealth_, carryingCap_, carryingCapMax_})
```

**Figure 5.** Equilibrium in the presence of workers (Commoners) and non-workers (Elites) with equal consumption per person. Simulation of HandyEquit1.

In Figure 5, the sum of worker and non-worker populations reaches the maximum carrying capacity. The optimal depletion factor in this society is bigger than that of an egalitarian society analyzed in the previous section. This is due to an increased amount of production required from the workers to sustain the non-workers.

*Scenario HandyEquit2: “Oscillatory Approach to Equilibrium”*

If the depletion factor is further increased to  $\text{depletFactor} = 2.64 * \text{depletFactorEq}$  we obtain an oscillatory behavior. The results are shown in Figure 6

```
model HandyEquit2
  "Equitable society Scenario Equit2:
  Oscillatory Approach to Equilibrium"
  extends HandyEquitableBase;
  initial equation
    elite = 25;
  equation
    depletFactor = 2.64 * depletFactorEq;
end HandyEquit2;
```

We simulate and plot:

```
plot({commoners_, elites_, nature_,
wealth_, carryingCap_, carryingCapMax_})
```

**Figure 6.** Oscillatory convergence to equilibrium with tolerable overshoot. Simulation of HandyEquit2.

Now, the carrying capacity (`carryingCap`) is lower than the maximum carrying capacity, but the total population approaches a steady state value after an oscillatory phase.

*Additional Scenarios in an Equitable Type of Society*

There are also scenarios HandyEquit3 “Cycles of Prosperity, Overshoot and Collapse”, HandyEquit4 “Full Collapse”, and HandyEquit5 “Preventing a Full Collapse by Decreasing Average Depletion per Capita”.

The reader is encouraged to also try these models, which include experimenting with different values of the depletion factor, and in the case of HandyEquit5, increasing the ratio of non-workers to workers.

#### 4.5 Simulation Scenarios of an Unequal Society—Elites and Commoners with Different Access to Wealth

The unequal society appears to be closer to the status of our current world. The inequality factor `ineqFactor` is made to vary from 10 to 100 in the unequal scenarios.

We will reproduce a pair of experiments intended to show the effects of changing birth rates and inequality as a means for moving from an unsustainable to a sustainable mode of behavior.

```
partial model HandyUnEquitableBase
  "Uneq Scenarios: Unequal Society (with
  Elite and Commoners)"
  extends HandyBase(ineqFactor = 100,
    depletFactorEq = 0.00000667,
    birthRComm = 0.03, birthRElite = 0.03);
end HandyUnEquitableBase;
```

*Scenario HandyUneq2: “Full Collapse”*

In this scenario the inequality factor is set very high: `ineqFactor = 100`. Also, the initial seed for the population of the Elite is set to `elite = 0.2` and a large depletion factor (including pollution effects) `depletFactor = 1E-4` is selected. The result is a full collapse with no recovery, as shown in Figure 7 below.

```
model HandyUneq2
  "UnEquitable society Scenario Uneq2:
  Type-II Collapse (Full Collapse)"
  extends HandyUnEquitableBase(ineqFactor
    = 100,
    depletFactorEq = 0.00000667,
    birthRComm = 0.03, birthRElite = 0.03);
  initial equation
    elite = 0.2;
    commoners = 100.0;
  equation
    depletFactor = 15 * depletFactorEq;
end HandyUneq2;
```

```
plot({commoners_, elites_, nature_,
wealth_, carryingCap_, carryingCapMax_})
```

**Figure 7.** Full collapse due to over-depletion and high levels of inequality (`ineqFactor=100`). Simulation of HandyUneq2.

As soon as the Commoners' population surpasses the carrying capacity, *wealth* starts to decline and never again recovers. Before disappearing, Elites remain insensitive to the wealth's fast decrease for a long period after the Commoners' population starts its massive decline. This is possible due to the unequal access to wealth, which is a hundred times larger than that of the Commoners.

#### Scenario *HandyUneq3*: "Soft Landing to Optimal Equilibrium"

In this scenario several parameters and initial values are changed with respect to the previous case.

- Inequality is reduced by a factor of ten, yielding `ineqFactor = 10`.
- The depletion factor is set to its equilibrium value, derived analytically: `depletFactor = depletFactorEq = 6.35E-6`, much lower than in the previous scenario.
- The initial values for the population are set as `commoners=10 000` and `elite=3000`.
- The birth rates are assumed to be controllable and selected as `birthRComm=0.065` and `birthRElite=0.02`.

The results are shown below:

```
model HandyUneq3
  "UnEquitable society UnEquit3: Soft
  Landing to Optimal Equilibrium"
  extends HandyUnEquitableBase(ineqFactor
    = 10, depletFactorEq = 0.00000635,
    birthRComm = 0.065, birthRElite =
    0.02);
  initial equation
    elite = 3000.0;
    commoners = 10000.0;
  equation
    depletFactor = depletFactorEq;
end HandyUneq3;
plot({commoners_, elites_, nature_,
wealth_, carryingCap_, carryingCapMax_})
```

**Figure 8.** Unequal society reaching a sustainable equilibrium with moderate inequality (`ineqFactor=10`) and birth rate control. Simulation of *HandyUneq3*.

The new set of parameters produces a sustainable equilibrium in an unequal society. It represents an example of implementation of policies that simultaneously limit inequality and allow birth rates to remain below critical levels. In this model inequality and birth rate are separate but simultaneous measures. In fact, in the real world high birth rates in poor societies are often a consequence of inequality.

#### Additional Scenarios for an Unequal Type of Society

There are also scenarios *HandyEquit1* "Collapse with Recovery of Nature" and *HandyEquit4* "Oscillatory Approach to Equilibrium", which perform experiments with different values of the depletion factor, birth rates, and values of initial populations.

## 5 A Short Look at the World3 Model

*World3* is a rather complex world model and therefore, its realm, scope, and objectives are quite different from those of *Handy*. The compiled version contains 41 state variables and 245 algebraic variables, with the same number of equations, representing many facets of human society and global ecological and economic dynamics.

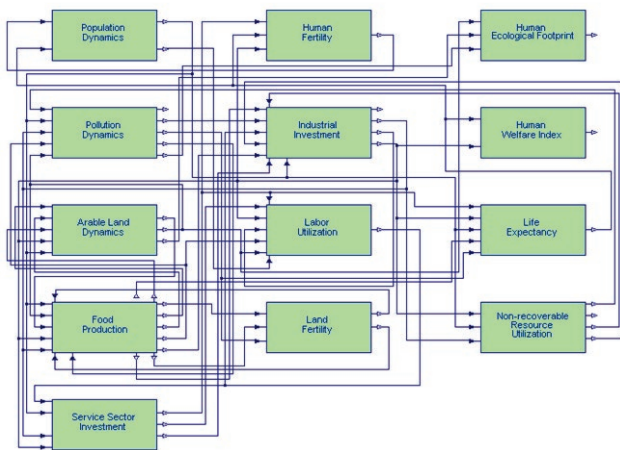

The model is available as part of the *SystemDynamics.WorldDynamics* library [1], developed by François Cellier and his students. They made a documented Modelica version of *World3* by translating the original model from its version in Stella.

The *SystemDynamics.WorldDynamics.World3* model is represented as a Modelica package that implements Meadows et al *World3* model. *World3* was first described in the 1972 book *Limits to Growth: A Report for the Club of Rome's Project on the Predicament of Mankind* [5]. The book has seen two later editions, one published in 1992 (20-year edition), and the most recent one published in 2004 (30-year edition) [7]. Each of these new editions were accompanied by an updated model. The model in this Modelica *World3* version is the newest model discussed in the 2004 edition *Limits to Growth: The 30-Year Update*.

Whereas Jay Forrester listed his entire mathematical model in his book *World Dynamics*, Meadows et al in *Limits to Growth* only discussed the results obtained using their model. The mathematical model itself was not listed. The main reason was to make the book more accessible to a wider public. Another reason is that *World3* is considerably more complex than *World2*, and consequently, a thorough discussion of all aspects of the model would have taken up much more space in the book. Instead, the authors published a separate book of 637 pages in 1974: *Dynamics of Growth in a Finite World* [6] that describes all facets of the model.

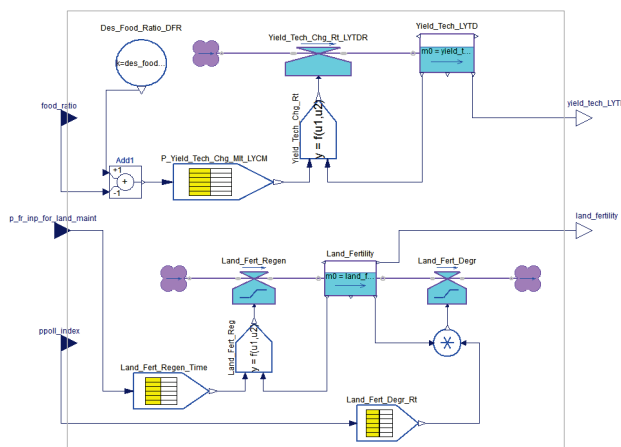

Since the World3 model is rather complex, it was subdivided into 13 different sectors (i.e., submodels) describing aspects of the following: 1) arable land dynamics, 2) food production, 3) human ecological footprint, 4) human fertility, 5) human welfare index, 6) industrial investment, 7) labor utilization, 8) land fertility, 9) life expectancy, 10) non-recoverable resource utilization, 11) pollution dynamics, 12) population dynamics, and 13) service-sector investment.

In the overall main model, one submodel of each class is placed on the screen, and the individual submodels are connected appropriately (Figure 9).

**Figure 9.** Overall World3 model.

The submodel `World3.Land_Fertility`, for example, is depicted below in Figure 10.

**Figure 10.** A submodel of World3: `SystemDynamics.World3.Land_Fertility`.

This submodel has 3 Inputs and 2 outputs. Two state variables, `Land_Fertility` and `Yield_Tech`, are represented by means of “Level” blocks, which have the ability to accumulate. Levels play the role of the state variables in a differential equation. Levels are in turn driven by the input and/or output “Rates” connected to the left and right sides, respectively, determining the velocities at which the accumulated quantity increases

or decreases. These Rates, in turn can be functions of other variables, including the state of the Level itself. Said functions are defined and interconnected following a block diagram approach, resorting to a vast library of pre implemented blocks such as Non-Linear Functions, Table Lookup Functions, Gains, Multipliers, etc.

The “Clouds” connected to the rates have only a pictorial purpose, expressing the fact that a source and/or a sink always exists with the physical ability to provide and/or absorb material without limits. The latter can be considered the conceptual “boundaries” of the model, as no detail is given for the processes taking place in material supply or consumption at these ends.

Whereas the World2 model lumps the entire population into a single state variable, the World3 model offers a demographic population dynamics model that distinguishes between children and adolescents, young adults of child-bearing age, older adults who are still integrated into the work force, and the retired population.

The capital investment is subdivided into investments in the military/industrial complex, in the service sector, and in agriculture.

Both the natural resources and pollution models have been upgraded by including changes in technology as factors influencing the depletion of resources and the release of pollutants. This is meaningful as improved technology may enable us to use the available resources more efficiently, and may also make it possible to produce goods in a cleaner fashion.

### Scenarios with World3

The book *Limits to Growth: The 30-Year Update*, describes eleven scenarios based on different sets of assumptions. These scenarios are also part of the Modelica World3 model. We shall briefly discuss three of these scenarios:

- **Scenario1** is the so-called “Standard Run”. This is the original World3 model with basic assumptions and without any adjustments.
- **Scenario2** is the same as **Scenario1**, but with twice as much non-recoverable resources initially available, i.e., more oil, coal, metal, etc.
- **Scenario9** is based on **Scenario2** but applies a number of measures to avoid collapse and to try to transform the human society into a sustainable one.

The three scenarios are simulated between year 1900 and 2200.

Unfortunately, both **Scenario1** and **Scenario2** lead to population collapse rather quickly, as depicted in Figure 11. Doubling the non-renewable resources in **Scen-**

nario2 does not help at all (it delays the collapse, but makes it steeper). The population increases a little further, but the subsequent collapse is even more severe, primarily due to increased levels of pollution. The current developments in our world unfortunately seem to be rather close to Scenario2.

If a collapse indeed should occur, will it be as quick as depicted in Figure 11? That must not necessarily be the case. The World3 model assumptions may not be completely valid during such a stressful transition period. Political decisions, rationing policies, etc., may lead to decreasing resource consumption and create a slower, more controlled contraction to a sustainable level of consumption.

**Figure 11.** The world population according to Scenarios 1, 2, and 9 in the World3 model.

How can a collapse be avoided? Scenario9 applies the following aggressive technology development plan:

- Increased industrial resource efficiency, i.e., a reduction in the use of non-renewable material and energy, a 4% resource decrease/year.
- Arable land protection, e.g., to decrease and prevent land erosion, and to preserve existing land.
- Agricultural yield enhancement, a 4% increase/year.
- Pollution reduction, a 4% decrease/year.

Additionally, a program for birth control is implemented with an average number of two children per family. The scenario furthermore assumes that there is a certain capital cost to implement these technologies, and that 20 years are required for their full implementation.

The Scenario9 simulation to year 2200 shows a sustainable society. However, if the simulation continues to the year 2500, we observe that it is hard to maintain sustainability with a large human population combined with high standards of living. If the size of the population is gradually decreased back to its level of about a hundred years ago, the chances for being able to maintain high standards of living are much better.

Another issue is model validity. A number of assumptions behind the World3 model may not be valid that far into the future. However, one fact is certain: the human race must, in the long run, live sustainably on planet Earth due to limitations in resources, energy, and space. Consumption overshoots like the current one can only be temporary.

## 6 Conclusion

The Handy model has the remarkable feature of providing a minimal structure helpful for intuitive understanding of the human-nature interaction. It can produce a rich variety of dynamical modes, leading to non-trivial scenarios. This combination is seldom found in most world models, where the quest for including more details comes at the price of lack of intuitiveness.

Handy is very useful as a “conceptual” model that can trigger varied interpretations and discussions comparing qualitatively different scenarios.

However, the goal of Handy is not to make quantitative short-term forecasts of the world state, but to assess qualitatively the impacts of various factors such as inequality and depletion on the long-term behavior of human societies.

The explicit stratification of social classes guides the interpretations to an essential playground needed to discuss the fate of human population.

Also worth mentioning is the fact that human societies developed a degree of cultural and technological complexity that prevents treating them in the same way as an animal species.

Accumulation of wealth (human’s ability to save throughout generations) is a major distinction which *allows* for irreversible population collapses, whereas with predation only, the predator-prey type of models can only produce cyclic oscillations (i.e., partial collapses).

Several senior modelers have remarked that it is not reasonable to expect that any world model will correctly predict how the world will develop after the onset of collapse, as unpredictable social disruptions and/or restructurings would result that invariably invalidate most of the model’s assumptions, parameters and even structures that might have described pre-collapse phases in a credible way. Such social reshaping will have its dynamics determined by interactions between different social classes, and in that regard, again, the Handy approach of disaggregating them in at least two strata represents a valuable contribution to future world modeling.

Moreover, we want to draw the reader’s attention to the aggregation made in Handy of natural renewable and non-renewable resources into a stock variable. This

paves the way for attaining scenarios that look sustainable in the very long run (i.e., when simulating “to infinity”). Based on the principles of thermodynamics it can be shown that in the long run the maximum carrying capacity of humans on earth will be determined *only* by the remaining renewable resources (once we have depleted all the non-renewables for good).

If we consider renewable and non-renewable resources independently of each other (along with the commoners, the elites, and their inequality factor), we may be able to use the resulting world model to investigate scenarios that offer possible answers to an additional highly relevant question. How should we best use the non-renewable resources to attain a society with minimum inequalities, for when the time comes that humanity must rely on renewable resources only? To investigate such a goal, the inequality factor should be altered from a constant parameter to a variable. Although models presented in this paper are from different classes (minimal Handy vs. more complex, realistic world model, World3), their conclusions are similar. In the long run, not so far into the future, humanity must change to living sustainably on planet Earth. This change can occur either as a planned gradual transition, preserving well-functioning societies, or as a more disruptive, unplanned transition resulting in a less pleasant society with a reduced ecological capacity.

## Abstract

Cellular Automata (CA) can be used to describe dynamic phenomena dependent of the spatial coordinates. This approach exhibits two main advantages: CA models are conceptually simple and can be simulated very efficiently. A new Modelica library named *CellularAutomataLib* is presented. It facilitates describing one- and two-dimensional CA in Modelica, and interfacing these CA models with other Modelica models. Simulation performance and large model support have been highest priority in the design of the library. To achieve these goals, the CA internal description is programmed in C and it is consequently hidden to the modeling environment, which is released from the burden of causalizing and manipulating the millions of equations that typically compose CA models. The library architecture and use are discussed in this manuscript. Two examples illustrate the library use: heat diffusion on a chip and spread of an epidemic disease. *CellularAutomataLib* is freely available at <http://www.euclides.dia.uned.es>.

**Keywords:** *Cellular Automata, Hybrid Models, Modelica*

## 1 Introduction

Cellular Automata (CA) are discrete and dynamic models initially proposed by John Von Neumann for the study of self-reproducing automata [1]. These models are represented as a grid of identical volumes, named cells, that can be in any finite number of dimensions [2]. The state of each cell in the automata is discrete, and it is updated at discrete time steps during the simulation following a transition function or rule. This rule constitutes a function of the current state of the cell and the state of its neighbors, and

defines the state of the cell for the next time step [3]. The neighborhood of a cell is usually composed of a selection of its surrounding cells, but not necessarily. It can be defined in different ways, such as the Moore's neighborhood that includes all the surrounding cells; the von Neumann's neighborhood that includes the cells adjoining the four faces of one cell; or the extended von Neumann's that also includes each cell just beyond one of the four adjoining cells [4].

Formally, CA can be defined as a tuple [5]:

$$CA : \langle T, X, \Omega, S, \delta, Y, \lambda \rangle$$

where  $T$  is the time base (isomorphic with  $\mathbb{N}$ );  $X$  is the input set;  $\Omega$  is the set of all input segments  $\omega$  (an input segment may be restricted to a domain  $T$ ,  $\omega : T \rightarrow X$ );  $S$  is the state that is the same for all cells because the cellular space is homogeneous;  $\delta : \Omega \times S \rightarrow S$  is the global transition function used to update the state of each cell ( $\delta(\omega, s_i) \rightarrow \delta_l(N_i)$ ,  $\delta_l$  is the uniform local transition function,  $s_i$  is the state of the  $i$ -th cell of the grid and  $N_i$  is the set of states that correspond to the neighborhood of the  $i$ -th cell, usually defined as a set of offsets from  $i$ );  $Y$  is the output set; and  $\lambda : S \rightarrow Y$  is the output function used to observe the state of the automata.

The application of CA in the study of systems is broad and diverse, mainly due to the simplicity of describing these kind of models (i.e., by describing the state of the cell, the initial state of the space and the transition rule) and the computational efficiency of their simulation. They have been used to model systems in medicine [6], architecture [7], chemistry [8], economics [9], biology [10], among many others [11].

The feasibility for describing CA models using the Modelica language was demonstrated by Fritzson [12]. He described the Conway's Game of Life model

in Modelica by representing the cellular space using a matrix of integer numbers. The initial conditions are set using a vector that contains the coordinates of the initially active cells. At discrete times, generated using a *sample* operator, the state of the automata is updated by iterating the whole matrix using two *for* loops, and using the transition function to update each individual cell. The model uses the Moore's neighborhood. In this model, the description of the cellular space and the evaluations of the transition function in each cell are coupled, diffculting its reutilization to describe other automata.

Another approach to describe CA models in Modelica was performed by the authors [13]. The *CellularPDEVS* package, distributed with the DESLib library [14, 15], supports the description of CA using the Parallel DEVS formalism [16, 17]. DESLib is freely distributed under the Modelica License 2, and can be downloaded from the Modelica Association website. The cellular space is represented as coupled Parallel DEVS models, and each cell is described as an atomic Parallel DEVS model. *CellularPDEVS* allows the user to focus on describing the behavior of the cell and the characteristics of the cellular space. The state of each cell corresponds to the state of the atomic Parallel DEVS model and can be represented using an arbitrarily complex Modelica data structure. The transition rule corresponds to the internal transition function of each cell, which can contain any Modelica algorithm. This approach facilitates the description of the model by making the simulation algorithm of the automata transparent to the user.

*CellularPDEVS* also facilitates the combination of CA models with other Modelica models. Inputs and outputs to the cellular space can be described using the external transition and output functions, respectively. These functions (i.e., internal transition, external transition and output) are used in the DEVS formalism to define the behavior of models. However, the performance and the scalability of this library are not satisfactory. The reasons are twofold. First, the size of CA models is typically in the order of hundreds of thousands and millions of equations. The translation of models with so large number of equations (when even possible) is time consuming and huge executable files are generated (see also discussion in [18]). Second, long event chains are executed to update the CA state. The complete model is reevaluated after executing each event in the event chain, which in most cases is unnecessary, degrading the simulation performance significantly.

A new library, named *CellularAutomataLib*, for describing CA models is presented in this manuscript. The objective of this new library is to preserve the characteristics of *CellularPDEVS*, in terms of facility to describe the behavior of the model and the characteristics of the space, and provide a solution for its main drawbacks (i.e., simulation performance and scalability). *CellularAutomataLib* is not based in the Parallel DEVS formalism. The CA model (i.e., the state of the cell and the transition function) is described as a C data structure (i.e., a C *struct*) and a function. Its simulation algorithm is also directly implemented into several C functions that are called from Modelica by using the external function interface provided by the language [19]. CA models defined in this way are not manipulated by the Modelica tool (Dymola in our case), which produces an smaller simulation code and avoids the reevaluation of the whole model after the treatment of an event in the CA. The user can focus on describing the behavior of the model and not the simulation algorithm. Also, the simulation of CA models automatically displays a graphical animation that is generated using Gnuplot [20]. *CellularAutomataLib* provides interface models that facilitate the connection of CA with other Modelica models. These interface models use user-defined external functions to translate the state of the cell into a standard Modelica data type that can be used in other models, and vice-versa. The library has been developed using Dymola FD1 2013 on an Intel Core i5 2.3GHz machine with 16GB of RAM and running Linux 3.11 x86\_64.

The structure of the manuscript is as follows. The architecture of the library and its design principles are detailed in Section 2. The procedure to develop new CA models using the library is described in Section 3. The description of the interface models used to combined CA with other Modelica models is given in Section 4. Two case studies of 2D CA models are presented in Section 5. Finally, some conclusions and future work ideas are given in Section 6.

## 2 Architecture of the Library

The architecture of *CellularAutomataLib* is shown in Fig. 1. The library is composed of the following models and packages: License (description of the license); User Guide (library documentation); Path\_gnuplot (path to Gnuplot binary, used to generate the graphical animation); Input\_Region model (used as interface between CA models);

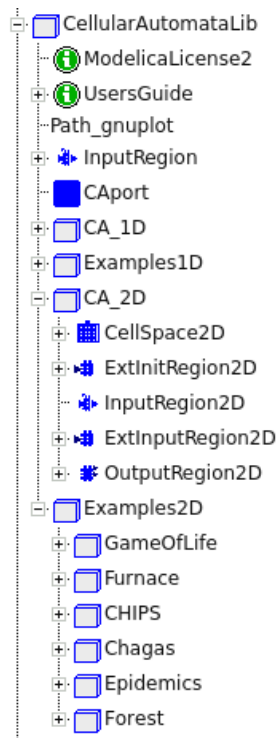

Figure 1: Architecture of *CellularAutomataLib*.

CAport connector (used to connect CA models with other models); CA\_1D package (models to describe 1D CA); Examples1D package (examples of 1D CA); CA\_2D package (models to describe 2D CA); Examples2D package (examples of 2D CA).

The library has been implemented using C functions that are called from Modelica functions using the external function interface. The basic functions that perform the simulation of the automata are included in the file *CellularAutomataLib.c*, which should not be modified by the user. These functions include the creation and initialization of the space, the simulation of a step or the reception of an external input, among others. The behavior of the model has to be described as external C code (i.e., *model.c*).

### 3 Development of New Models

A CA model in *CellularAutomataLib* is composed of one or several *cellular spaces*, that represent the 1D or 2D grid of cells, and some models, named *interface models*, used as interface between cellular spaces or between cellular spaces and other models. Cellular spaces and interface models include functions that call external C functions. These external C functions are used to describe the behavior of the

Figure 2: Relationship between Modelica and external C code in *CellularAutomataLib*.

models. The relationship between the external code and the Modelica code is summarized in Fig. 2. In this section the development of new cellular spaces is described. The use of the interface models is described in Section 4.

#### 3.1 Description of New Cellular Spaces

A cellular space in *CellularAutomataLib* is composed of the cellular space model and some functions. The cellular space model is a partial model that describes the one- or two-dimensional space represented by the automata. The parameters of the model are shown in Table 1. The cellular space model includes three replaceable functions: *Create*, that is used to create the cellular space, allocate memory for the cells and set them to the default state; *Initial*, that is used to initialize the cells indicated using the *init\_cells* parameter and; *Rule*, that represents the transition function and is used to update the state of the cells at each simulation step.

The behavior of the cellular space is described by redeclaring these functions with functions that call external C functions (cf. Fig. 2). The description of these external functions is detailed below.

At the beginning of the simulation, the cellular space model creates the space using the *Create* function, and initializes the cells included in the *init\_cells* parameter. After that, it performs periodic simulation steps every *Tstep*

Table 1: Parameters of cellular space models.

Name	Description
space_nrows	defines the number of rows of the space (only used in 2D spaces).
space_ncols	defines the number of columns of the space.
neighborhood	defines the topology of the neighborhood. It contains a list of the relative positions of the neighbors from the center cell.
n_inputs	defines the number of inputs received from interface models connected to the automata.
wrapped_borders	defines the boundary conditions. In 1D spaces it is either 1 for wrapped or 0 for non-wrapped. In 2D spaces it can be 0 for non-wrapped, 1 for wrapped only north-to-south, 2 for wrapped only east-to-west and 3 for wrapped in all directions.
Tstep	defines the interval between two steps in the simulation of the automata.
Initial_step	defines the time for performing the first simulation step.
plot_animation	defines if the graphical animation is generated (value 1) or not (value 0).
plot_range	defines the maximum value of the variable displayed in the animation. Thus, the displayed variable can be in the $[0, plot\_range]$ interval.
display_delay	defines a delay in the graphical animation that can be used to improve its visualization, which otherwise could be too fast to be observed.
init_cells	defines a list of coordinates of the cells that will be initialized at the beginning of the simulation.
name	defines a name for the automata that will be displayed in the graphical animation.

time, starting at  $time = Initial\_step$  (i.e.,  $sample(Initial\_step, Tstep)$ ).

### 3.2 Description of External C Functions

In order to facilitate the description of the behavior of new cellular spaces, the library includes a template file (named `draft.c`) that can be used to describe the required external C functions.

Following the formal specification of the automata, the user has to define the state variables that represent the state of the cells ( $S$ ) and the model behavior (i.e., the transition function  $\delta$ ) by reimplementing the functions included in the `draft.c` file, into a new file (e.g., `model.c`). The time base  $T$  is set using the parameters `TStep` and `Initial_step` of the cellular space model. The rest of the elements of the tuple  $(X, \Omega, Y, \lambda)$  are defined using the interface models.

As an example, the development of the Rule 30 model described by Wolfram [4] is presented. The transition function for this model is shown in Fig. 3.

The `draft.c` file can be used as a template to describe the behavior of the model. It has been renamed as `wolfram.c` for this example. The state of each cell is defined as an `int` value by modifying the `State` data type in the template. The default value for the cell state will be set using the `DefaultState` function, and so it has to be modified to set the

Figure 3: State transitions for the Rule 30 model.

default state to 0. The state of initialized cells will be set using the `InitialState` function, and so it has to be modified to set the initial state to 1. The transition function shown in Fig. 3 has to be implemented by modifying the transition function in the template. In order to automatically generate the graphical animation, the `Display` function in the template has to be modified to convert the state of the cell (i.e., the `State` data type) into a double value.

The cellular space for the Rule30 model is described in Modelica by extending the `CellSpace1D` model from `CellularAutomataLib`. The `Create`, `Initial` and `Rule` functions are redeclared using functions that call the external C functions defined in `wolfram.c`. The parameters for the Rule30 model are: `Space_ncols = 20`, `neighborhood = {-1,1}`, `wrapped_borders = 1`, `Tstep = 1`, `Initial_step = 0`, `plot_animation = 1`, `plot_history = 1`, `init_cells = 10`, `name = "Rule 30"`. The graphical

animation will be automatically generated using Gnuplot if `plot_animation` is set to 1. In this model, state 0 is displayed in black, and state 1 is displayed in yellow. The first 10 steps of simulation for the Rule 30 model are shown in Fig. 4 (the number of step is represented in the vertical axis).

Figure 4: Simulation of the first 10 steps for the Rule 30 model.

## 4 Interfacing with Other Models

*CellularAutomataLib* includes several interface models that facilitate the combination of CA with other Modelica models. The inputs of the CA model ( $X, \Omega$ ) are described using *input* and *external input* region models. The outputs of the CA model ( $Y, \lambda$ ) are described using the *output* region model. Their behavior and use are detailed below.

### 4.1 Input Region

Cellular spaces can be combined to increase the modeling functionality of the library. This communication can be performed using the *Input\_Region* model. The same model can be used between 1D and 2D spaces.

The combination is performed by translating the state of some cells from one space as inputs for the other. The prototype of the transition function in C includes a vector of the received inputs, in order to allow the user to manage them. Each *Input\_Region* has associated an input identifier, set using the parameter `input_id`, that can be used as index for the vector of inputs of the transition function.

The *Input\_Region* model has two interface ports: *FROM* and *TO*. These interface ports are used to connect to the involved cellular spaces. The state of the cell  $[i, j]$   $i \in [\text{RstartFrom} : \text{RendFrom}]$ ,  $j \in [\text{CstartFrom} : \text{CendFrom}]$ , in the *FROM* space, is translated using

the `SetInput` function into an input for the cell  $[m, n]$   $m \in [\text{RstartTo}, \text{RstartTo} + (\text{RendFrom} - \text{RstartFrom})]$ ,  $n \in [\text{CstartTo}, \text{CstartTo} + (\text{CendFrom} - \text{CstartFrom})]$  in the *TO* space. `RstartFrom`, `RendFrom`, `CstartFrom`, `CendFrom`, `RstartTo` and `CstartTo` are parameters of the model. In 1D spaces, only the column parameters are used (i.e., `CstartFrom`, `CendFrom` and `CstartTo`). An additional parameter, named `column_1D_2D`, allows to use a 1D region as a column, instead of a row, of inputs for a 2D space. The communication is started at `time = comm_start` and is performed every `comm_rate` time.

The function `void SetInput(int Fspace, int Frow, int Fcol, int Tspace, int Trow, int Tcol, int input_id)` from the `draft.c` file can be used to redeclare the `SetInput` of this model.

### 4.2 External Input Region

Similarly to the *Input\_Region* model, the model *ExtInputRegion* can be used to set an input to a region of cells in the automata. In this case, the input is generated using an external signal instead of the state of the cells of other automata.

The model receives an external Real input signal through port *u*, which is used as input for a region of cells in the automata connected to port *TO*. As in the previous interface model, a 2D region is defined by the positions between `Rstart` and `Rend` (for the rows) and `Cstart` and `Cend` (for the columns). In 1D regions only the parameters referring to columns are considered. The input is assigned to the position `input_id` of the vector of inputs which is available for the user in the transition function. The external signal can be observed in the following ways (defined by the parameter `Input_type`), in order to be converted into an input:

- *Quantizer*: the input is set every time the value of the signal changes in a defined value or quantum.
- *Cross\_UP*: the input is set every time the value of the signal crosses a defined threshold in the upwards direction.
- *Cross\_DOWN*: the input is set every time the value of the signal crosses a defined threshold in the downwards direction.
- *Cross\_ANY*: the input is set every time the value of the signal crosses a defined threshold in any direction.

Figure 5: Example of behavior of external input region, external init region and output region models.

- *Sample*: the input is set periodically using the sample operator.

The signal is translated into an input using the function `ExtInput`, that can be redeclared using the `void ExtInput(int space, int row, int col, double value, int input_id)` function included in `draft.c`.

An example of external input is shown in Fig. 5. The `ExtInputRegion` model, connected to the CA `CASpace`, is used to set the state of the cells in the fifth row of the cellular space to the value of its input `const` (i.e., 5). The values of the states of the cells are graphically represented at the right of the figure.

### 4.3 External Init Region

This model can be used to set the initial state of a region of cells in the space using the value of an external signal. The model has an input port, named `u`, where a Real signal is received, and a port named `T0` that connects to the CA. This signal is translated, using the `ExtInit` function, into a cell state that will be used to initialize the cells in the region of the automata connected to port `T0`.

The 2D region is defined by the positions between `Rstart` and `Rend` (for the rows) and `Cstart` and `Cend` (for the columns). Only the column parameters are considered for 1D regions. The `ExtInit` function can be redeclared using the `void ExtInit(int space, int row, int col, double value)` function included in `draft.c`.

An example of external init is shown in Fig. 5. The `extInitRegion` model is used to initialize the state of the

cells in the rows 1 to 4 (and columns 1 to 5) with the value of its input `const1` (e.g., 0).

### 4.4 Output Region

The `OutputRegion` model can be used to observe the state of the cells in a region of the automata connected to port `FROM`. The state is translated into an output Real signal that can be used by other Modelica models. As in the previous interface models, a 2D region is defined by the positions between `Rstart` and `Rend` (for the rows) and `Cstart` and `Cend` (for the columns). In 1D regions only the parameters referring to columns are considered.

The model contains two output Real ports, `y` and `yM[Rend-Rstart+1, Cend-Cstart+1]` (being `yM[Cend-Cstart+1]` for the 1D case). Depending on the value of the parameter `Output_type`, the state is observed in different ways:

1. (AVERAGE): the value of `y` is calculated as the average value of the states of the cells in the `[Rstart : Rend, Cstart : Cend]` interval, or `[Cstart : Cend]` for 1D.
2. (MAX): the value of `y` is calculated as the maximum value of the states of the cells in the `[Rstart : Rend, Cstart : Cend]` interval, or `[Cstart : Cend]` for 1D.
3. (MIN): the value of `y` is calculated as the minimum value of the states of the cells in the `[Rstart : Rend, Cstart : Cend]` interval, or `[Cstart : Cend]` for 1D.

4. (MATRIX): the value of the state of the  $i, j$ -th cell in the space is assigned to  $yM[m, n]$  (where  $m = 1 : (Rend - Rstart + 1)$  and  $n = 1 : (Cend - Cstart + 1)$ ). In 1D, the  $i$ -th cell is assigned to  $yM[n]$  (where  $n = 1 : (Cend - Cstart + 1)$ )

The value of the state is translated into a Real value using the `ExtOutput` function, that can be redeclared using the double `Output(int space, int row, int col)` function included in `draft.c`.

An example of output region is shown in Fig. 5. The `outputRegion` model is used to calculate the maximum value (i.e., `Output_type = MAX`) among the states of the cells in the first column of the space. In the case shown in the figure, the output port `y` of `outputRegion` is set to 5.

## 5 Case Studies

*CellularAutomataLib* includes several examples of 1D and 2D models, whose purpose is to demonstrate the functionality of the library and to facilitate the development of new models. The modeler can use these examples as a base for constructing new CA. Two of these examples are described in this section: a model of heat transfer on a chip and a SIR (Susceptible Infected Removed) epidemic spread model.

### 5.1 Heat Transfer on a Chip

The model describes the flow of the heat generated in a chip by the execution of software instructions. Two heat transfer mechanisms are considered: heat diffusion in the chip surface and convective heat flow from the chip surface to the air. The model contains two bi-dimensional CA: one describes the chip and the other describes the air. The software execution is modeled using power sources located at certain points of the chip surface. These points correspond to the position of the circuit components (ALU, memory, etc.) that dissipate more heat.

The structure of the CA model is shown in Fig. 6. This model combines two cellular spaces, one for the chip (named *Chip*) and another for the air (named *Air*), with other Modelica models used to represent the sources of power (named *T+3S+N*, *Pg1* and *Pg2*). Two external input region models (named *Pext1* and *Pext2*) are used to combine the external sources of power with the *Chip* cellular space. Two input regions are used to represent the transfer of heat between chip and air (named *Chip2Air*), and vice-versa (named *Air2Chip*). An external init region (named *InitTemp*) is

Figure 6: CA model of heat transfer on a chip.

Table 2: Parameters of the chip model.

Name	Value	Unit	Description
gamma	100	$\frac{W}{m^2 \cdot K}$	Heat transfer coefficient
cp	710	$\frac{kg \cdot K}{m^3}$	Specific heat capacity
ro	2330	$\frac{kg}{m^3}$	Average density
rows	10	-	Number of rows
cols	10	-	Number of columns
length	0.005	<i>m</i>	Layer length
width	0.005	<i>m</i>	Layer width
thickness	0.0001	<i>m</i>	Layer thickness
k	149	$\frac{W}{m \cdot K}$	Thermal conductivity

used to initialize the cells of *Chip* at 20°C, given by a constant source from the Modelica Standard Library. Finally, an output region model (named *chipTEMP*) is used to observe the evolution of temperatures in the chip.

The model has been implemented into a C file, named *chip.c*. The equations that describe the heat transfer have been implemented in the transition function of *Chip*. The *Air2Chip* model sets the temperature of the Air as an input for *Chip*, which is used to calculate the convection of heat from the chip to the air. The *Pext1* and *Pext2* set two inputs for *Chip* that are used as input heat flows in the equations.

The transition function calculates the evolution of temperatures in the chip using two alternatives: a forward Euler and a leap-frog integration algorithms. These are explicit integration algorithms that are easily

(a) Euler integrator

(b) Leap-frog integrator

Figure 7: Simulation results for cell [1,3] and error between Modelica and CA models: a) using Euler integration; and b) using Leap-frog integration.

included in the transition function of the CA. At each step of the simulation the transition function calculates an integration step and updates the values of the temperatures. The interval between steps using the forward Euler has to be  $0.0001s$  in order to ensure stability. That interval can be increased to  $0.001s$  using the leap-frog algorithm.

An analogous model has been developed using Modelica. In this model, the space has been discretized using finite volumes. In order to perform a comparison between the Modelica and the CA models, each volume will be represented by a cell in the CA.

Both models, Modelica and CA, have been simulated for  $10s$  using the parameters shown in Table 2. The simulation results at the cell [1,3] and the error between the Modelica and CA approaches

Figure 8: Capture of the graphical animation for the chip CA model.

Table 3: CPU time (in seconds) for integration of models during  $10s$  of simulated time.

Model	Grid Side Size			
	10	50	100	200
Modelica (DASSL)	0.02	15.3	506	error
Modelica (EULER)	1.26	1225	5046	-
CA (EULER)	22	1670	6720	-
CA (LEAP-FROG)	2	173	711	2790

Table 4: Number of equations for the *Chip* model.

Model	Grid Side Size			
	10	50	100	200
Modelica	$1.2e^3$	$2.7e^4$	$1.1e^5$	$4.4e^5$
CA	$1.7e^3$	$2.5e^3$	$1e^4$	$4e^4$
CA without <i>chipTEMP</i>	70	70	70	70

are shown in Fig. 7. A capture of the graphical animation is shown in Fig. 8. The evolution of the simulation time with respect to the size of the grid is shown in Table 3. The simulation using EULER integration for the  $200 \times 200$  grid was not performed and thus it does not appear in the table. The number of equations in the Modelica and CA models are shown in Table 4. If the *chipTEMP* output region model is removed from the CA model the number of equations is 70, independently of the grid size. The Modelica model rapidly reaches the maximum number of equations that can be efficiently handled by Modelica/Dymola, while the number of equations in the CA model remains lower. Note that Dymola

fails, due to an unknown internal error, to compile the Modelica model in a grid of 200x200 cells.

## 5.2 Epidemic Spread

The dynamics of epidemic spread are modeled in this example. This model was proposed in [21]. It is a SIR model where susceptible (S), infected (I) and recovered (R) individuals are considered. The evolution of the number of these individuals is defined by Eqs. (1), (2) and (3).

$$I_{ij}^t = (1 - \varepsilon) \cdot I_{ij}^{t-1} + v \cdot S_{ij}^{t-1} \cdot I_{ij}^{t-1} + S_{ij}^{t-1} \cdot \sum_{(\alpha, \beta) \in V} \frac{N_{i+\alpha, j+\beta}}{N_{ij}} \cdot \mu_{\alpha\beta}^{i,j} \cdot I_{i+\alpha, j+\beta}^{t-1} \quad (1)$$

$$S_{ij}^t = S_{ij}^{t-1} - v \cdot S_{ij}^{t-1} \cdot I_{ij}^{t-1} - S_{ij}^{t-1} \cdot \sum_{(\alpha, \beta) \in V} \frac{N_{i+\alpha, j+\beta}}{N_{ij}} \cdot \mu_{\alpha\beta}^{i,j} \cdot I_{i+\alpha, j+\beta}^{t-1} \quad (2)$$

$$R_{ij}^t = R_{ij}^{t-1} + \varepsilon \cdot I_{ij}^{t-1} \quad (3)$$

where  $V$  is the neighborhood of the  $(i, j)$  cell, and  $\mu_{\alpha\beta}^{i,j} = c_{\alpha\beta}^{(i,j)} \cdot m_{\alpha\beta}^{(i,j)} \cdot v$ , where  $c_{\alpha\beta}^{(i,j)}$  and  $m_{\alpha\beta}^{(i,j)}$  are the connection factor and the movement factor between the  $(i, j)$  cell and its neighbor cell  $(i + \alpha, j + \beta)$ , and  $v \in [0, 1]$  is the virulence of the epidemic. The parameter  $\varepsilon$  defines the portion of infected individuals that recover from the disease at each step.

This model has been programmed in a C file, named `epidemics.c`. The size of the cellular space has been set to 50x50 in order to validate its results with the ones presented in [21]. Only the cell in the center of the space (i.e., position [25,25]) is initialized at the beginning. The parameters are set using the values:  $\varepsilon = 0.4$ ,  $v = 0.6$ ,  $c = 1$  and  $m = 0.5$ . The Moore's neighborhood is used. The CA model includes the cellular space model and three output region models (see Fig. 9), used to sum the values of the state variables (S, I and R) of the whole CA. Each output region model redefines the `ExtOutput` function using a different function from `epidemics.c`, in order to observe the desired variable. The simulation results after 50 steps are shown in Fig. 10.

In order to demonstrate the simulation of a larger space, this model has been simulated with an space size of 500x500. This generates around 750,000 equations, due to the matrices defined in the output region models. These matrices are managed by the Modelica simulation algorithm. Dymola generates a C file of 140MB which is difficult to compile and simulate. Because of this the output region models

Figure 9: CA model of SIR epidemics spread.

Figure 11: Capture of graphical animation at  $t = 100$  for the epidemic spread model using a 500x500 grid.

are removed from the CA model before performing the simulation. The capture of the graphical animation at the final step ( $t = 100$ ) is shown in Fig. 11.

## 6 Conclusions

A new Modelica library has been developed to facilitate the description of CA models. The simulation algorithms are transparent to the user, who has to focus on the description of the behavior of the model. The behavior of the models is described using external C functions. The use of external functions improves the performance and scalability of the simulations. The functionality of the library has been demonstrated by means of two case studies.

Some future work ideas are: to support the description of 3D models; to improve the generation of the graphical animation using graphical libraries instead of Gnuplot; to develop a graphical interface to define the initial conditions of the CA model; and to automatically parallelize the simulation of the CA in order to improve the performance.

## Abstract

Physiolibrary is a free open-source Modelica library designed for modeling human physiology. It is accessible on the Modelica Libraries web page at <https://www.modelica.org/libraries>. This library contains basic physical laws governing human physiology, usable for cardiovascular circulation, metabolic processes, nutrient distribution, thermoregulation, gases transport, electrolyte regulation, water distribution, hormonal regulation and pharmacological regulation.

*Keywords: Physiolibrary; HumMod; Modelica library; Physiology; Integrative physiology; System biology*

## 1 Introduction

Our laboratory have a long tradition building physiological libraries, starting with the Matlab/Simulink environment [2]. The origin of this Modelica Physiolibrary was in the first version of our HumMod Golem Edition model implementation [3-6], where it was called HumMod.Library. As the successors of Guyton's Medical Physiology School write, the original HumMod model [7] is "The best, most complete, mathematical model of human physiology ever created" [8].

We are also developing many types of smaller physiological models for use in medical education [9-11], so it was essential to separate this library from our HumMod Modelica implementation. Some other Modelica models and libraries covering the biological domain already existed, e.g. [12-17], which are useful in the process of system modeling and parameter identification. Especially BioChem Modelica library, that implements large part of SBML library in Modelica language [14-18].

Our Physiolibrary contains only carefully-chosen elementary physiological laws, which are the basis of more complex physiological processes. For example from only three type of blocks (ChemicalReaction, Substance and MolarConservationMass) it is possible to compose the allosteric transitions [19] or the Michaelis-Menten equation.

## 2 Physiology

Physiology is a very progressive discipline, that examines how the living body works. And it is no surprise that all processes in the human body are driven by physical laws of nature. The great challenge is to marry old empirical experiments with the "new" physical principles. Many teams and projects in the word deal with this formalization of physiology, for example: Physiome[20], SBML[17, 18], EuroPhysiome[21], VPH[22], CellML[23] etc. It is our hope that this library helps this unflagging effort of physiologists to exactly describe the processes.

### 2.1 Display units in physiology

Energy in medicine and chemistry has a very long tradition. One must not be confused by its different units and definitions. The researcher must be aware of multiple definitions of calorie, such as the international calorie, the 15°C calorie, the thermal calorie or the Calorie with a capital "C". The origin of this unit is in the thermal energy needed to heat one gram of water by one degree Celsius. But because the measurement conditions may differ, these alternative definitions are necessary. In physiology it is recommended to use only international calorie as defined in Table 1. The flow of heat/energy is usually calculated in kcal/min, but in physics this is called power and is expressed in the SI unit watts.

Pressure units in medicine are also mainly based on historical measurements. For many years blood

pressure was measured by the mercury sphygmomanometer, where the pressure is represented by the change of mercury hydrostatic column height. And because the scale of units on the column is in millimetres the pressure unit is called millimetre of mercury 'mmHg'. There also exists a very small difference between this unit and torrs. It is caused again by variance in measurement conditions.

**Figure 1, Example parameter dialog for non-SI physiological units. The Dymola environment automatically converts this user's non-SI-values to SI-values to ensure compatibility with any other Modelica library.**

Many physiological processes are based on electrical principles in the human body. The main cause of this is that each cell has a nonconductive membrane with molecular structures called channels, through which the fluxes of electrolytes can be precisely regulated. Even more, the cells use energy from metabolism to retain a small electric potential between inside and outside. This view leads to a unit called equivalents or "eq". A charge of 1eq, for example, has 1mol of sodium cations ( $\text{Na}^+$ ). The fluxes of electrically charged ions can be in meq/min, but in physics the SI unit ampere is more generally used.

Unit conversion table (for Modelica environment display-unit setting)			
x kcal	=	4186.8*x	J
x kcal/min	=	69.78*x	W

x mmHg	=	133.322387415*x	Pa
x degC	=	273.15 + x	K
x meq	=	96.4853365*x	C
x meq/min	=	1.60808894*x	A
x mosm	=	0.001*x	mol
x litreSTP	=	0.044031617*x	mol
x litreSATP	=	0.040339548*x	mol
x litreNIST	=	0.041571200*x	mol

**Table 1, Selected Non-SI units in physiology**

Another strange unit describing the amount of substance is the osmol ("osm"), which has the same value as the mol, but which highlights the property that this substance cannot cross the membrane together with the flux of its solvent.

For gases, it is common to measure the amount as volume, which for specific measurement conditions is equivalent to the number of molecules. The International Union of Pure and Applied Chemistry (IUPAC) set this standard condition for temperature and pressure (STP) precisely at 0°C and 100kPa. But other standards exist. For example, SATP is measured at 25°C and 100kPa, or the standard measurement condition at the National Institute of Standards and Technology (NIST), which is 20°C and 101.325kPa.

## 2.2 Chemical domains in physiology

In physiology books, chapters about chemical substances are organized by their types. The main reason for this is that each substance in the human body is regulated in a different way. For example the regulation of sodium is different from the regulation of potassium, and from the regulation of glucose, and so on. This view leads to the idea of having separate models of each substance. The origin of different flows and regulations is the (cellular) membrane. Water and solutions can cross it in different directions at the same time. Crossings occur for different reasons: water is driven mostly by osmotic gradients, electrolytes are driven by charge to reach Donnan's equilibrium, and some solutes can even be actively transported against their concentration or electrical gradients. And all this is specifically driven from the higher levels by neural and hormonal responses.

In Physiolibrary flows and fluxes of solutes are supported mostly by the Chemical package. All parts inside this Physiolibrary.Chemical package use the connector ChemicalPort, which defines the molar concentration and molar flow/flux rate of one solute. This is the supporting infrastructure for modeling membrane diffusion, accumulations of substances,

reversal chemical reactions, Henry's law of gas solubility, dilution with additional solvent flow, membrane reabsorption, chemical degradation and physiological clearance.

For usage examples, please open the Chemical.Examples package, where the chemical reaction shown in Fig. 2 is implemented, along with many other chemical processes.

**Figure 2, Example of a chemical reaction:  $A \leftrightarrow B + C$ .** Purple beakers (Substance) accumulate one type of substance and generate its concentration in port. Block for chemical reaction (ChemicalReaction) can have any number of substrates or products with any stoichiometric numbers. In this case there is only one substrate and two products. Purple lines represent chemical connectors, are composed of molar concentration and the molar flow of substance.

The graphically-created diagram shown in Fig. 2 generates this Modelica code:

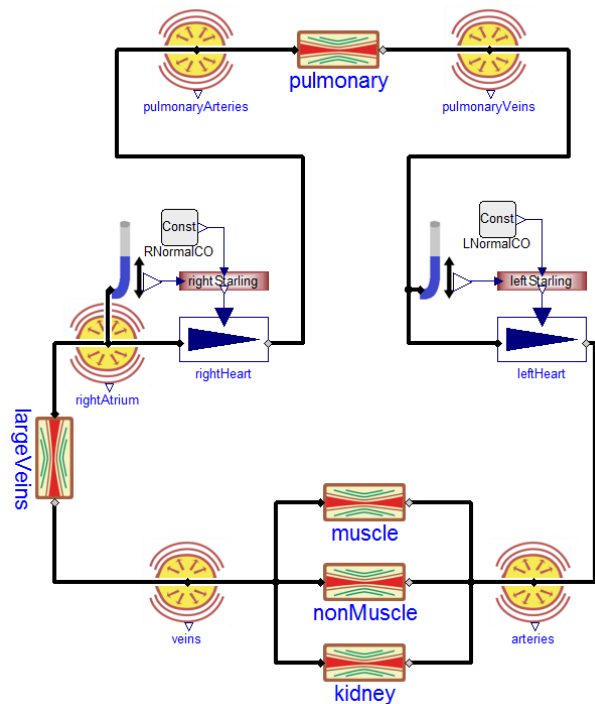

```
model SimpleReaction2
import PhysiLibrary.Chemical.Components.*;
Substance      A(solute_start=0.9);
ChemicalReaction reaction(K=1, nP=2);
Substance      B(solute_start=0.1);
Substance      C(solute_start=0.1);
equation
connect(A.q_out, reaction.substrates[1]);
connect(reaction.products[1], B.q_out);
connect(reaction.products[2], C.q_out);
end SimpleReaction2;
```

This means that before the numerical simulation begins, each Substance.solute\_start parameter must be set to some initial amount of substance. ChemicalReaction.nP must also be configured for the number of products, and parameter ChemicalReaction.K must be configured for the dissociation constant of reaction in SI-units (please note that concentration of  $1 \text{ mol/m}^3 = 1 \text{ mmol/L}$ ). As mentioned before, the values in text code are in SI-units, but the Dymola environment support non-SI units in the parameter dialog of each component.

### 2.3 Hydraulic domain in physiology

The main usage of the hydraulic domain in human physiology is modeling of the cardio-vascular system. And because there are no extreme thermo-

dynamic conditions, the system can be really simple—it is only necessary to model conditions for incompressible water, at normal liquid-water temperatures and with relative pressure 5-20kPa. This boring thermodynamic state leads to using very simple blocks of hydraulic resistance, hydrostatic pressure, volumetric flow, inertia and finally a block representing blood accumulation in elastic vessels.

**Figure 3, Hydraulic example: the cardiovascular subsystem of the famous Guyton-Coleman-Granger model [1].** Yellow circles (ElasticVessel) represent blood accumulation and pressure generation, rectangles between them are hydraulic resistances (Resistance) of blood vessels, blue triangles (Pump) represent a heart pump driven by the Frank-Starling law. Heart-filling pressures are determined by the block with the blue tube icon (PressureMeasure) and a block-rectangle (Blocks.Factors.Spline) converts filling pressure to their effect on cardiac output. Black lines connect the hydraulic connectors (HydraulicPort), which contains pressure and volumetric flow variables.

### 2.4 Thermal domain in physiology

For the human body to function optimally, it is critical to hold the core temperature at  $35\text{--}39^\circ\text{C}$ . A fever of  $41^\circ\text{C}$  for more than a short period of time causes brain damage. If the core temperature falls below  $10^\circ\text{C}$ , the heart stops. As in the hydraulic domain, the thermal domain is simplified to these conditions.

The PhysiLibrary.Thermal package extends the package Modelica.Thermal.HeatTransfer from

Modelica Standard Library 3.2 (MSL), where the connector is composed of temperature and heat flow. The main blocks in `Physiolibrary.Thermal` are: `Conductor`, `IdealRadiator` and `HeatAccumulation`. The heat conductor conducts the heat from the source, such as muscles or metabolically active tissue, to its surrounding. `IdealRadiator` delivers heat to tissues by blood circulation. `HeatAccumulation` plays a role in accumulating thermal energy in each tissue mass driven by its heat capacity. We recommend using this block instead of `Modelica.Thermal.HeatTransfer.HeatCapacitor` to allow the possibility of variable mass amounts, and to have support for calculating steady state, described in section 2.7.

**Figure 4, Example of heat flow from a working muscle.** The muscle is represented by a red beaker (`HeatAccumulation`), where heat energy is accumulated in a mass with defined weight and specific heat. Heat transfer is processed by blood circulation (`IdealRadiator`) with blood flow as its internal parameter. The temperature of blood is set to a fixed value of 37°C to simulate well-regulated core body temperature.

**Figure 5, Basic heat flow model of human body.** Heat production occurs in each tissue via metabolism, or from warm (to cool) eaten food using the MSL block

with two red arrows (`Modelica.Thermal.HeatTransfer.Sources.FixedHeatFlow`). This heat is stored in tissues (`HeatAccumulation`) and transferred out by blood (`IdealRadiator`) or together with mass (`Stream`, `HeatOutstream`), where the model also integrates vaporization heat loss. Heat radiation and conduction to the environment is simplified using an MSL block for heat conductor (`Modelica.Thermal.HeatTransfer.Components.ThermalConductor`).

## 2.5 Osmotic domain in physiology

One of the basic phenomenon of biological systems is the osmotically-driven flow of water. This is always connected with semipermeable membranes. The different concentrations of impermeable solutes on both sides of the membrane causes the hydrostatic pressure at the concentrated side to rise[24]. This pressure difference is called osmotic pressure. Osmotic pressure is linearly proportional to the concentration gradient of impermeable solutes. The osmolarity (osmotic concentration) is also one of the main indexes of human body balance, called homeostasis. Its value should not significantly deviate for a long period of time from a value of 285-295mosm/l.

In `Physiolibrary` the osmotic connector `OsmoticPort` is composed of the osmotic concentration and the volumetric flux of permeable liquid. The two main blocks are called `Membrane` and `OsmoticCell`. Here, inside the membrane blocks, it is of course possible to also define hydraulic pressure and temperatures effects on both sides of membrane.

**Figure 6, Osmotic example simulating water transfer between intracellular and interstitial compartments in hypertonic or hypotonic conditions.**

## 2.6 Types and units

The most common errors in `HumMod Golem Edition` were caused by using bad physical units. The main problem of medical research, articles, and experiments is using obscure units from medicine, pharmacology, biology and non-physics disciplines.

The `Physiolibrary` fulfills the `Modelica` ideal of using SI units as the main unit for each variable, and the previously described physiological units are also implemented as the `displayUnits` for each variable. Using these `displayUnits` the user sets and sees the "physiological" values. The implementation can also be joined to any unit-correct `Modelica` models and physical equations without crashing due to unit in-

compatibilities. The unit support of PhysiLibrary is so strong that one can even chose the right unit-typed "input real"/"output real" from the library package `Types.RealIO` or one can use unit-typed constants (`Types.Constants`). As can be expected, only the non-specific package Blocks in the PhysiLibrary has variables without units.

## 2.7 Steady states

One of the main questions in clinical medicine is how to stabilize the patient. In modeling the oscillating heart, breathing, circadian rhythm or menstruation cycle the model can be designed as non-oscillating, using variables such as period times, amplitudes, frequencies, mean values and other phase space variables. This type of model has better numerical stability for long simulation times, and even more importantly, it can be "stabilized". This stabilization we call a steady state.

To be mathematically exact, we define a *steady state system* (SSS) as a non-differential system derived from an original differential system (DS) by using zero derivations and by adding additional steady state equations (ASSE). The number of the ASSE must be the same as the number of algebraically dependent equations in the non-differential system derived from DS by setting zero derivations. The ASSE describes the system mostly from the top view, such as the equations of mass conservation laws or the boundary equation of environment sources.

To define a model as an SSS, the user must switch each Simulation parameter in each block to the value `Types.SimulationType.SteadyState` and must have correctly defined all necessary ASSE. This setting causes the system to ignore any start values for any state and add zero derivation equations instead. There does not currently exist a Modelica environment which can automatically find and remove generated dependent equations by this solution. So the correct number of states must be marked as dependent (parameter `isDependent`) and the same number of ASSE must be inserted. However, despite the fact that a model in this steady-state setting will not be locally balanced, it must be globally balanced and without any dependent equation.

**Figure 7, Steady state system example: equilibrium of chemical reaction  $A \leftrightarrow B + C$  is calculated with two ASSE. Zero change of reactant A is automatically propagated through a reaction to both products. So both products must be marked as dependent (parameter `isDependent`), and two mass conservation laws must be added as green square blocks to the right (`MolarConservationLaw`). Please note that conservation laws must be included only after designing the rest of the system, because they are global properties, not properties of individual substances or reactions.**

Adding an ASSE is possible by inserting and connecting the energy or mass conservation law block from package `SteadyState.Components`. Another possibility is using environment sources blocks, where setting the `isIsolatedInSteadyState` parameter adds the equation of the zero mass/volume/energy flow from or to environment.

The steady state model often changes to one big nonlinear strong component, but without solver stiff or convergence problems. Especially in quick chemical kinetics, it is not necessary to have very rapid molar fluxes, when it always reach equilibrium in the end. This design is also useful in creating steady-stated parts in a dynamical model without huge rebuilding. It also brings other benefits. To see these possibilities, one has to realize that conservation laws could be invariances in a dynamical simulation. This is really useful for debugging.

For example see the model `SteadyStates.Examples.SimpleReaction2_in_Equilibrium` (Fig.7), which implements the equilibrium of the closed system from Fig.2 as a solution of three chemical substances with a simple reversible reaction between them extended by two conservation laws. Each of these laws describes the total possible amount of one product in its free form and in its associated form.

It is always a big challenge to nicely solve initial values of differential system. However, it should be possible to solve the SSS in its initial phase. And this is the idea behind the `Types.SimulationType.InitSteadyState` option for models already extended with ASSE.

## 2.8 File utilities—input/output manipulations

During the creation and debugging of huge integrated models it is necessary to easily define consistent input, output and test sets of all output variables for some subsystems. Let's imagine that we have a model composed only of subsystems that converge from some constant inputs to constant outputs. It should be possible to substitute each main subsystem for its chosen constant output values as parameters. Comparing the model with these parametric values and the original subsystem can show the wrong part of the simulation.

For example in the huge HumMod model it is necessary to debug smaller parts separately. These tools could be use, because HumMod is the type of constant-converged model. Each subsystem in the first level has the constant input values set for its output variables. Simulating, for example, the cardiovascular subsystem is possible by creating the high-level system with the original cardiovascular subsystem, but with a constant metabolic, constant thermoregulation, constant hormonal, constant water, constant proteins, constant gases, constant electrolytes and constant status subsystem.

Because the number of output variables for each subsystem changes during development, it is a good idea to have only one list for each subsystem. And generating consistent sets to store, restore, compare initial and final values is possible by the same pattern as presented in the package Types.Example. In this package it is also possible to define a customized way to save and load the variables that connect subsystems together. For this purpose, one has to redeclare the package Types.Utilities with simple functions for reading and writing values, such as is done in the default package FileUtilities.

The typical code of a parameter set could be:

```
model MyParameterSet
  replaceable package T = Physiolibary.Types.RealTypes
    constrainedby Physiolibary.Types.RealTypes;

  T.Pressure      v1(varName="Bone-Flow.PO2");
  T.VolumeFlowRate v2(varName="Bone-Flow.BloodFlow");
  T.MolarFlowRate v3(varName="Bone-Metabolism.O2-Need");
  T.Volume        v4(varName="Bone-Tissue.LiquidVol");

  BusConnector busConnector;

equation
  connect(v1.y, busConnector.Bone_PO2);
  connect(v2.y, busConnector.Bone_BloodFlow);
  connect(v3.y, busConnector.Bone_O2Need);
  connect(v4.y, busConnector.Bone_LiquidVol);
end MyParameterSet;
```

To redefine these sets of values to use inputs from a file is simple. The user just redeclares the type of the values to type InputParameter and redirects reading functions to FileUtilities:

```
model InputParameterSet
  extends MyParameterSet( T(redeclare block Variable =
    Physiolibary.Types.RealExtension.InputParameter (
      redeclare package Utilities = Physiolibary.Types.FileUtilities));
  end InputParameterSet;
```

And the same set of values can also be redefined to file output at the end of the simulation:

```
model OutputFinalSet
  extends MyParameterSet( T(redeclare block Variable =
    Physiolibary.Types.RealExtension.OutputFinal (
      redeclare package Utilities = Physiolibary.Types.FileUtilities));
  end OutputFinalSet;
```

## 3 Conclusion

In our opinion the best way to understand this library is to download it from the Modelica web pages at [www.modelica.org/libraries](http://www.modelica.org/libraries) and examine the examples. We recommend examining the package *Hydraulica.Examples*, which provides an example of a simplified cardiovascular system; the package *Chemical.Examples*, which provides an example of allosteric hemoglobin oxygen binding; the package *Osmotic.Examples*, which simulates cell volume in hypertonic and hypotonic environments; and finally the package *Thermal.Examples*, which simulates the heating of circulated blood inside active muscles.

## Acknowledgements

This paper describes the outcome of research that has been accomplished as part of a research program funded by the Ministry of Industry and Trade of the Czech Republic by the grant FR—TI3/869 and by The Ministry of Education, Youth and Sports by the grant SVV-2013-266509.

In addition, the main author wants to thank Jan Obdržálek for consultations about physical units, and Austin Schaefer for English language editing.

## Abstract

The more-electric aircraft has been identified as the dominant trend for the future aircraft. With the development of power electronics, advanced control and drive systems, a great increase number of new electrical loads will be seen on-board. This paper presents an electrical power system (EPS) library developed in Modelica based on the dynamic phasor concept. The developed library uses a modular modelling concept. This makes the library more flexible and user-friendly. The application of developed library is also demonstrated through simulations of a MOET-architecture EPS.

*Keywords: Dynamic Phasor; More-Electric Aircraft; Modelica*

## 1 Introduction

The more-electric aircraft (MEA) has been identified as a dominant trend for the next-generation aircraft. The recent advance of power electronics, electrical drives and modern control theory makes it possible to replace many functions, which are conventionally managed by hydraulic, pneumatic and mechanical power, with electrical power driven devices [1]. This move offers reduced overall system weight, as well as increased efficiency, reliability and performance of the aircraft. The future EPS may take many forms: AC, DC, hybrid, frequency-wild, variable voltage, together with the possibility of novel connectivity topologies. To address the stability, availability and capability issues as well as to assess the performance of the power quality and transient behaviour, extensive simulation work is required to develop the EPS architectures.

Due to the switching behaviour of power electronic devices and its resulted higher harmonics, it is very

time-consuming and even impractical to simulate a large-scale EPS with some non-linear and time-varying models. Considering the system dynamic frequency is normally much lower than that of higher harmonics, it is a common practice to neglect these higher harmonics when studying system dynamic behaviour. The average modelling technique, which removes the higher harmonics by averaging the variable during one fundamental period, has been widely used to model the EPS recently. In these average models, the variables are transformed from the three-phase *abc* frame to a synchronous rotating *dq* frame (DQ0 models). The DQ0 model demonstrates good performance and high efficiency under balanced conditions [2]. This model, however, becomes very slow under unbalanced or faulty conditions. This is due to the second harmonic present in the DQ0 model under unbalanced conditions.

In this paper, a general averaging modelling technique, referred to as dynamic phasors (DP), is introduced and a model library based on this concept is developed in Modelica. The DPs are in nature some time-varying Fourier series coefficients. Compared with conventional phasors, the DP can model the system even it is not in the steady state. Truncating unimportant higher order harmonics and only considering the significant components, DP models are capable of retaining the dominant dynamic features of the EPS and suitable for transient performance studies. The slow variation of DPs allows for larger simulation time steps and results in faster simulations under both balanced and unbalanced conditions.

The software used to develop models is Dymola, standing for dynamic modelling laboratory. This software uses the open Modelica modelling language which allows users to freely create their own model libraries or modify the ready-made model libraries. This modelling language has been widely

used in modelling electrical power systems [3, 4]. In contrast to data flow-oriented languages with directed inputs and outputs, such as the widely known Matlab/Simulink tool, Modelica employs an equation-based modelling technique and all the variables are treated equally. This avoids the algebraic loop issues frequently occurred in Matlab/Simulink. The equation-based modelling concept also results in a faster modelling process and a significantly increased re-usability, since the interconnection between models is easier and simpler than that of the signal-flow based modelling. There is no need to explicitly define the interface equations and predefine the input and output signals.

In this paper, the dynamic phasor concept is briefly introduced. The development of DP models in Modelica is explained using an RLC circuit. DP models of key EPS elements, such as generators, PWM converters etc. are introduced. The application of the DP library is demonstrated through simulation of the MOET architecture EPS.

## 2 Dynamic Phasors

Before introducing the developed library, a brief introduction of the dynamic phasor concept is introduced in this section. The DPs essentially are some time-varying Fourier coefficients. For a time-domain quasi-periodic waveform  $x(\tau)$ , defining a time-moving window  $\tau \in (t-T, t]$ , as shown in Figure 1, and viewing the waveforms in this window to be periodic, the Fourier expansion of the waveform in this interval can be represented by the following Fourier series [5]:

$$x(\tau) = \sum_{k=-\infty}^{\infty} X_k(t) e^{jk\omega_s \tau} \quad (1)$$

Figure 1 (a) Defined moving window at time  $t_1$  and  $t_2$ , (b) equivalent periodic signal at time  $t_1$

where  $\omega_s = 2\pi/T$  and  $T$  is the length of the window. Though the window length  $T$  can be an arbitrary value, it is common that the fundamental period of the signal is chosen to avoid the DPs spreading over the entire frequency axis.  $X_k(t)$  is the  $k$ th Fourier coefficient in a complex form and is referred to as a “dynamic phasor”. It is defined as follows:

$$X_k(t) = \frac{1}{T} \int_{t-T}^t x(\tau) e^{-jk\omega_s \tau} d\tau = \langle x \rangle_k \quad (2)$$

where  $k$  can be any integer and is called the DP index. The triangular pair ‘ $\langle \rangle$ ’ is used as the DP calculation symbols for any time-domain variables. In contrast to the traditional Fourier coefficients, these Fourier coefficients are time-varying as the integration interval (window) slides with time. The selected set of DPs, or  $K$  with  $k \in K$ , defines the approximation accuracy of the waveform. For example, for DC-like variables and signals the index set only includes the component  $k=0$ , and for purely sinusoidal waveforms, with the window length equal to one period gives  $k=1$ .

A key factor in developing DP models is the relation between the derivatives of the variable  $x(t)$  and the derivatives of  $k$ th Fourier coefficients given as:

$$\left\langle \frac{dx}{dt} \right\rangle_k = \frac{d\langle x \rangle_k}{dt} + jk\omega_s \langle x \rangle_k \quad (3)$$

It is important to notice that, the derivative term on the right side of (3) allows the DP to study the electromagnetic transients of the power system, not limited to steady-state studies. If we drop this derivative term and fix the DP index to be  $k=1$ , the DP will reduce to the traditional phasors, which is widely used to study steady-state or quasi-steady power systems.

## 3 Modelica Library

In this session, the DP library in Modelica will be introduced. An RLC circuit, which is used to represent the transmission line in many cases, has been chosen to illustrate the DP technique. DP models of other essential elements are detailed in our previous publications [6-10] and will be briefly reviewed in this session as well.

### 3.1 DP model of RLC circuits

The DP models of RLC components are based on their time-domain voltage dynamic equations. Using the DP definition and properties, the DP transformation can be achieved conveniently.

#### (i) Resistance element

The time-domain voltage equation for a resistor can be expressed by:

$$v = Ri \quad (4)$$

If the resistance  $R$  is constant and time invariant, it can be moved out from the integration symbol and we obtain the DP form as:

$$\langle v \rangle_k = R \langle i \rangle_k \quad (5)$$

In our model, the DP index is chosen at  $K=\{0,1\}$ , the DP model in Modelica is shown below:

```
model Resistor
  extends interface.Twopins;
  parameter Modelica.SIunits.Resistance R(start=1);
equation
  v0=R*i0;
  v1.re=R*i1.re;
  v1.im=R*i1.im;
end Resistor;
```

where  $v0$  and  $v1$  are corresponding to DPs  $\langle v \rangle_{0,1}$ .

#### (ii) Inductance element

The time-domain voltage equation for an inductor is written as:

$$v = L \frac{di}{dt} \quad (6)$$

The DP form of (5) can be obtained by employing the DP definition and its differential as:

$$\langle v \rangle_k = \left\langle L \frac{di}{dt} \right\rangle_k = L \frac{d\langle i \rangle_k}{dt} + j\omega L \langle i \rangle_k \quad (7)$$

In Modelica, the DP model for inductors is written as:

```
model Inductor
  extends interface.Twopins;
  parameter Modelica.SIunits.Inductance L=0.001;
  Real w;
  parameter Real f=50;
equation
  w=2*Modelica.Constants.pi*f;
  v0=L*der(i0);
  v1.re=L*der(i1.re)-w*L*i1.im;
  v1.im=L*der(i1.im)+w*L*i1.re;
end Inductor;
```

#### (iii) Capacitance element

The DP model for a capacitor can be derived the same way as that for the inductor and is written as:

$$\langle i \rangle_k = C \frac{d\langle v \rangle_k}{dt} + j\omega C \langle v \rangle_k \quad (8)$$

```
model Capacitor
  extends interface.Twopins;
  parameter Modelica.SIunits.Capacitance C(start=2e-7);
  parameter Real f(start=50);
  Real w;
equation
  w=2*Modelica.Constants.pi*f;
  i0=C*der(v0)+0*w*C*v0;
  i1.re=C*der(v1.re)-w*C*v1.im;
  i1.im=C*der(v1.im)+w*C*v1.re;
end Capacitor;
```

The application of the DP models in Modelica is very convenient. In reality, it even looks the same as the models in Modelica/Dymola standard libraries. A simple RLC circuit with all the elements modelled in DPs is shown in Figure 2.

Figure 2 DP represented RLC circuit in Modelica

Figure 3 Simulation results of DP-modelled RLC circuit

The simulation results of the circuit are shown below. As can be seen, the sinusoidal source in DP domain becomes complex constant DC source. The currents flowing through the inductor turn into constant in the DP model.

### 3.2 DP models of synchronous generators and control

The modelling of synchronous machines has been an important topic in power system engineering for many decades. Today there are a large number of different models used in different studies. The three-stage generator system in a conventional aircraft is simplified into a synchronous generator (SG). Figure 4 showed the SG with its controlling structure.

Figure 4 The equivalent circuit for the generating system in aircraft

The DP model of these machines is based on their time-domain voltage and flux equations. The fully detailed DP model of a synchronous machine has been can be found in [6] and will briefly introduced here. In DP domain, the synchronous machine can be modelled as:

$$\langle \mathbf{v}_{abc} \rangle_k = -\mathbf{r}_s \langle \mathbf{i}_{abc} \rangle_k + \frac{d\langle \boldsymbol{\lambda}_{abc} \rangle_k}{dt} + j\omega \langle \boldsymbol{\lambda}_{abc} \rangle_k \quad (9)$$

$$\langle \mathbf{v}_{dqr} \rangle_k = \mathbf{r}_r \langle \mathbf{i}_{dqr} \rangle_k + \frac{d\langle \boldsymbol{\lambda}_{dqr} \rangle_k}{dt} + j\omega \langle \boldsymbol{\lambda}_{dqr} \rangle_k \quad (10)$$

$$\langle \boldsymbol{\lambda}_{abc} \rangle_k = -\sum_m \langle \mathbf{L}_s \rangle_m \langle \mathbf{i}_{abc} \rangle_{k-m} + \sum_n \langle \mathbf{L}_{sr} \rangle_n \langle \mathbf{i}_{dqr} \rangle_{k-n} \quad (11)$$

$$\langle \boldsymbol{\lambda}_{dqr} \rangle_k = \sum_m \langle \mathbf{L}_{rs} \rangle_m \langle \mathbf{i}_{abc} \rangle_{k-m} + \sum_n \langle \mathbf{L}_r \rangle_n \langle \mathbf{i}_{dqr} \rangle_{k-n} \quad (12)$$

where  $\mathbf{L}_{ss}$  denotes the stator self-inductance matrix,  $\mathbf{L}_{rr}$  is the rotor self-inductance,  $\mathbf{L}_{sr}$  and  $\mathbf{L}_{rs}$  are the mutual inductance. The matrix  $\mathbf{r}_s$  is the resistance of stator windings and  $\mathbf{r}_r$  is the resistance of rotor windings.

The proportional-integral (PI) controllers can be converted into the DP domain with their state-space equations:

$$\dot{x} = k_i u \quad (13)$$

$$y = k_p u + x \quad (14)$$

where  $u$  is the input,  $x$  is the state variable, and  $k_p$  and  $k_i$  are the proportional and integral gains correspondingly. This equation can be converted into dynamic phasors as:

$$\frac{d\langle x \rangle_k}{dt} = k_i \langle u \rangle_k - jk\omega \langle x \rangle_k \quad (15)$$

$$\langle y \rangle_k = k_p \langle u \rangle_k + \langle x \rangle_k \quad (16)$$

The model of PI controller in modelica is written as:

```
model PI_DP
  Modelica.ComplexBlocks.Interfaces.ComplexInput u[2];
  Modelica.ComplexBlocks.Interfaces.ComplexOutput y[2];
  parameter Real kp;
  parameter Real ki;
  constant Real PI=Modelica.Constants.pi;
  Real w;
  Complex x[2];
  Real xre;
```

```
equation
  w=2*PI*f;
  //dc component
  der(xre)=ki*u[1].re;
  xre=x[1].re;
  x[1].im=0;
  y[1].re=kp*u[1].re+x[1].re;
  y[1].im=0;
  //second harmonic

### 3.3 Auto-transformer rectifier units

The multi-pulse rectifier unit is widely used to supply the HVDC bus in aircraft electrical power systems. The DP modelling of an 18-pulse auto-transformer rectifier unit (ATRU) has been discussed in our previous publication [11]. The symmetry of the ATRU is used to simplify the modelling process. The DP index for variables at the AC side terminals are set at  $K=\{1\}$ . For the DC terminal variables, the DP index is set at  $K=\{0\}$  which is equal to their time-domain values. The DP model of ATRU is shown in Figure 5 and Figure 6.

Figure 5 configuration of an 18-pulse ATRU

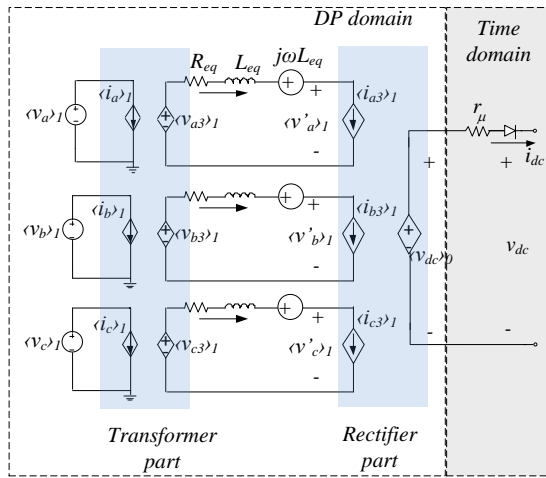

Figure 6 Equivalent circuit representation of DP model of an 18-pulse ATRU

### 3.4 Controlled rectifier units

The PWM controlled rectifier unit is well-known from previous publications and the topology is shown in Figure 7. With the voltage vector aligned with the  $d$  axis in a synchronous rotating frame, denoted as the  $DQ$  frame, the projections of the current vector onto the  $D$  and  $Q$  axes correspond to the active power and reactive power components respectively. This allows independent control of the active and reactive power flow. The electrical converter of the CRU is represented with the voltage and current relations in DP forms. The vector control of the CRU is transformed into DPs with the same strategy used in the controlled synchronous machines. The detailed development of the DP model for CRUs has been introduced in our previous publication [7]. component is considered. Thus, the DP index is set at  $K=\{0\}$ .

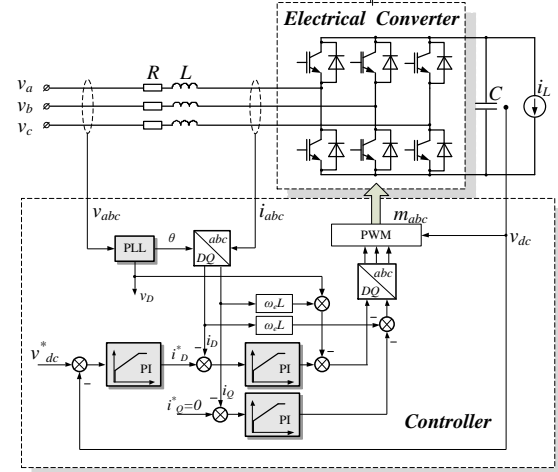

Figure 7 Structure of the PWM controlled rectifier

## 4 System Simulation

This simulation scheme has been shown in Figure 8. This EPS structure is based on the MOET large aircraft EPS architecture from Airbus France (document WP3.11 architecture V0 [12]). In the simulation studies, the electrical frequency of the SG1 is fixed at 400Hz and SG2 fixed at 405Hz. The HVAC bus voltages are controlled at 230V RMS. The power rating of elements in the system is shown in Table 1.

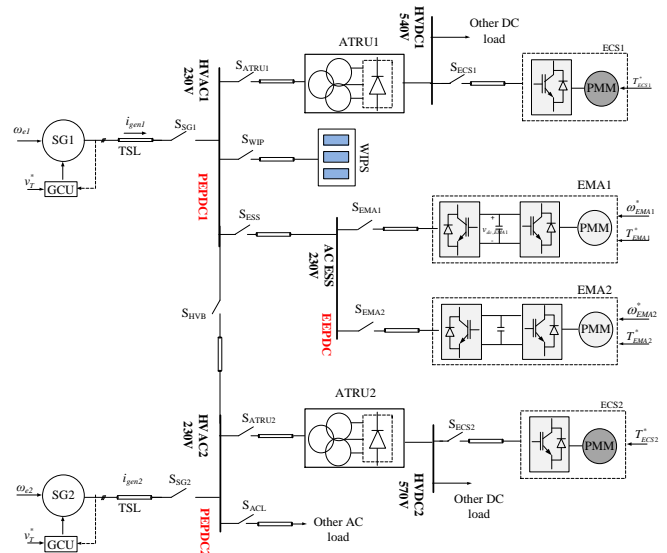

Figure 8 The EPS of the twin-generator aircraft

Table 1 Rated power of equipment in the example EPS

Equipment	Power rating
ATRU	150kW
WIPS	60kW
ECS	30kW
EMA	5kW
AC essential bus fed CRU	10kW
HVAC2 bus fed resistance	9kW
HVDC bus fed resistance	5kW

Table 2 Simulation scenarios of twin-generator aircraft EPS under normal operation conditions

Time (s)	Events
0.00	Simulation starts; EPS starts up
0.15	Switches $S_{SG1}$ and $S_{SG2}$ are closed; Switches $S_{ATRU1}$ and $S_{ATRU2}$ are closed; DC loads on HVDC buses are connected
0.20	ESC1 and ECS2 start to accelerate to the rated speed (3000rpm)
0.50	Rated load torques applied to ECS1 and ECS2 (95Nm)
0.70	WIPS changes from 60kW to 6kW
0.80	EMA1 and EMA2 start to accelerate to the rated speed (900rpm)
0.90	Rated load torque applied to EMA1 and EMA2 (54Nm)
1.00	SG1 and SG2 are connected
1.02	$S_{SG1}$ opens; SG1 removes from the system and SG2 covers the whole load system
1.20	Simulation ends

The simulation starts at  $t=0$ s. The GCU starts to regulate the HVAC bus phase voltage to 230Vrms. After the HVAC bus voltage reaches the steady state, the switches  $S_{ATRU1}$  and  $S_{ATRU2}$  are closed at  $t=0.15$ s. The SG1 starts to supply ATRU1 through HVAC1 bus. At the same time, the SG2 starts to supply ATRU2 through HVAC2 bus. At  $t=0.2$ s, the speed reference for two ECS drive system is set at 3000rpm and the rated load torque 95Nm applied to these ECS systems at  $t=0.5$ s. At  $t=0.7$ s, the

de-icing system starts to run at rated power and the WIPS is set at 60kW. After 50ms second, the de-icing process finishes and the power requirement of WIPS is reduced to 6kW to maintain the temperature of the aircraft wings. The DC-link voltage reference of EMA is set to 800V at  $t=0.6$ s. The speed reference of the EMA is set to rated speed 900rpm at  $t=0.8$ s with rated load applied at  $t=0.9$ s. In order to demonstrate parallel operation of the two generators,  $S_{HVB}$  is closed at  $t=1.0$ s. The two generators start to work in parallel for a short period, 20ms, then  $S_{HVB}$  opens and the two generators work separately again. The event sequence of start-up of the twin-generator aircraft EPS is also shown in Table 2.

Results from the ABC model (the model as a benchmark, in the three-phase coordination with switching behaviour) and DP models (all the elements are modelled in DPs) are compared in the following figures. The dynamic responses of ATRU-fed HVDC bus voltages,  $v_{HVDC1}$  and  $v_{HVDC2}$  are shown in Figure 9. The initial values of  $v_{HVDC1}$  and  $v_{HVDC2}$  are set at zero. At  $t=0.15$ s, when the switches  $S_{SG1}$  and  $S_{SG2}$ ,  $S_{ATRU1}$ ,  $S_{ATRU2}$  are closed, the inrush current push the DC-link voltage of ATRUs  $v_{HVDC1}$  and  $v_{HVDC2}$  from 0V to around 800V. From  $t=0.2$ s, the ECS starts to speed up and draws power from the generator. A slope voltage drop at HVDC bus can be noticed from this point. This is because the PMSM in the ECS acquiring a linearly increasing power from the generator as shown in Figure 10 and Figure 11. The linearly increasing AC currents resulted in correspondingly a linearly voltage drop in the transmission lines and at AC terminals of ATRUs. This results in a linear decrease of the DC voltage  $v_{HVDC1}$  and  $v_{HVDC2}$ . When the rated loads of ECS1 and ECS2 are applied, a slight voltage drop can also be seen in  $v_{HVDC1}$  and  $v_{HVDC2}$  at  $t=0.5$ s. The reduction of the WIPS power requirement at  $t=0.7$ s results in a higher  $v_{HVDC1}$  and  $v_{HVDC2}$ . When the generators SG1 and SG2 are connected,  $v_{HVDC1}$  and  $v_{HVDC2}$  decrease due to the difference between  $v_{HVAC1}$  and  $v_{HVAC2}$ . With SG1 removed from the system at  $t=1.02$ s, SG2 starts to supply the whole load system and the system comes to the steady state after a short transient period. The  $v_{HVDC1}$  and  $v_{HVDC2}$  from ABC and DP modelling techniques are well-matched as shown in Figure 9.

Since the system is assumed to be balanced, the currents flowing into ATRUs  $i_{ATRU1}$  and  $i_{ATRU2}$  are represented by the phase A current only. For comparison studies, the variables in the DP model are

transformed to the time domain. The simulation results of  $i_{ATRU1}$  and  $i_{ATRU2}$  are shown in Figure 10 and Figure 11. The currents  $i_{ATRU1}$  and  $i_{ATRU2}$  remains zero until the load connected to the HVDC buses at  $t=0.15$ s. The acceleration of PMSMs of ECS's induces the increasing of  $i_{ATRU1}$  and  $i_{ATRU2}$  starting from  $t=0.2$ s. The application of rated loads at ECS's introduces the step of  $i_{ATRU1}$  and  $i_{ATRU2}$ . It can be seen that the results from ABC and DP models are well matched during the whole simulation process. The magnitude of DPs  $\langle i_{ATRU1} \rangle_1$  and  $\langle i_{ATRU2} \rangle_1$  are also shown in Figure 10 and Figure 11. From these two figures, it can be seen that the magnitudes of  $\langle i_{ATRU1} \rangle_1$  and  $\langle i_{ATRU2} \rangle_1$  give the envelope of the result from the ABC model.

Figure 9 The dynamic response of  $v_{HVDC1}$  and  $v_{HVDC2}$ . Above: response of  $v_{HVDC1}$ ; below: response of  $v_{HVDC2}$

Figure 10 The dynamic response of  $i_{HVAC1}$ , phase A current flowing into ATRU1. Above:  $i_{HVAC1}$ ; below: zoom-in area of  $i_{HVAC1}$

Figure 11 The dynamic response of  $i_{HVAC2}$ , phase A current flowing into ATRU2 Above:  $i_{HVAC2}$ ; below: zoom-in area of  $i_{HVAC2}$

Figure 12 Dynamic response of drive loads, (a)  $\omega_{r\_ECS1}$  speed of PMSM of ECS1; (b)  $\omega_{r\_ECS2}$  speed of PMSM of ECS2; (c)  $\omega_{r\_EMA1}$  speed of PMSM of EMA1; (d)  $\omega_{r\_EMA2}$  speed of PMSM of EMA2

The speed of PMSMs of ECS1, ECS2, EMA1 and EMA2 is shown in Figure 12. The PMSMs are well controlled by their speed controllers. It presents well agreement between two modelling techniques.

Table 3 Comparison of the computation time between two different models

Model	ABC	DP
Simulation time (s)	7983	43
Acceleration	1	185

The computation time consumed by the two different models is compared in Table 3. It can be seen that the DP model is 185 times faster than the ABC model. The simulation time of ABC model is counted in hours compared with that of the DP model in seconds. Comparing the simulation time between the ABC and DP model, one can notice that the acceleration of DP model is significant. This is due to the fact that the variables are DC-like in the DP model which allows larger time steps in the simulation process. Another average modelling technique based using the  $dq$  frame (DQ0 model) can achieve the same acceleration order as that of DP model. However, the DQ0 model will lose its efficiency when the system is under unbalanced conditions. The DP model, on the other hand, can maintain its efficiency even the system is under unbalanced conditions. This merit of DP model has been demonstrated in our previous publications with subsystems of the aircraft EPS. Our future research will compare the three modelling techniques, ABC, DQ0 and DP models, with EPS system under MOET architecture.

## 5 Conclusion

The paper introduced a DP library for EPS studies. This library is developed in Dymola/Modelica. Based on the DP library established, a twin-generator EPS based on MOET architecture has been studied under normal conditions. The comparison between the ABC model and the DP model illustrated the accuracy of the developed DP model, during generator starting, parallel operation, load change and other events. The simulation time comparison revealed that the DP model is about 200 times faster than the ABC model. The accuracy and efficiency shows great potential of the DP modelling technique to be applied in EPS studies. In addition, since the DP modelling technique is essentially a frequency-domain modelling technique and its efficiency is not affected by the system condition, this allows the DP model a faster simulation speed even when the EPS is in unbalanced or faulty conditions. This merit of DP models will be shown in our future publications.

# Flexible modeling of electrical power systems – the Modelica PowerSystems library

Rüdiger Franke, ABB, Germany – Ruediger.Franke@de.abb.com,  
Hansjürg Wiesmann, Switzerland – HJ.Wiesmann@bluewin.ch

## Abstract

New trends such as renewable power, virtual power plants, electric mobility and smart grids raise the importance of electrical power systems. The systems are manifold, including e.g. DC, single- and multi-phase AC with fixed and variable frequency. Often times such systems cover other physical domains as well, such as rotational mechanics and thermo-fluid. Required system models range from simple flow calculations of active power to detailed transient and asymmetric studies of three-phase systems. Transformed modal coordinates play an important role for the treatment of three-phase AC systems.

The paper introduces the new Modelica PowerSystems library. It covers arbitrary phase systems in one modeling framework. Besides simple generic models that are valid with all phase systems, also large sets of detailed component models for DC and three-phase AC are included. The detailed component models have been ported from the former Spot library to PowerSystems.

The usefulness of the library is shown on behalf of manifold examples and applications carried out so far for power/frequency control, intraday optimization and virtual power plants as well as electrical drive trains of wind turbines.

## 1 Introduction

The Modelica Standard Library, version 3.2.1, contains the Electrical.Digital and Electrical.Analog sub-libraries, besides Electrical.Spice3 for digital and analog electronics. The Electrical.Multiphase and Electrical.Machines sub-libraries cover detailed

dynamic models of power electronics in the time domain [1]. The Electrical.QuasiStationary sub-library treats AC systems with complex phasors [2].

Some more electrical libraries have been developed during the last years by different authors. One of them, the Spot library, introduced a couple of important features, such as the uniform treatment of natural (abc) and modal (dq0) coordinates in one framework, making it well suited for the detailed modeling of transient effects [3]. Moreover the Spot library supported the per-unit system for parameterization and it contained an extensive set of component models.

Being well suited for detailed transient modeling of three-phase power systems, the Spot library has sometimes been considered overkill if simpler quasi-static models were sufficient. A further drawback of the Spot library was that the same models appeared multiple times in distinct sub-libraries for particular phase systems. The Spot library hasn't been available since Modelica version 3 anymore.

This paper introduces the new PowerSystems library that integrates the Spot library with a new concept of replaceable phase systems. The aim is to support different single and poly phase systems and different mathematical formulations in one framework. In particular this shall cover systems like:

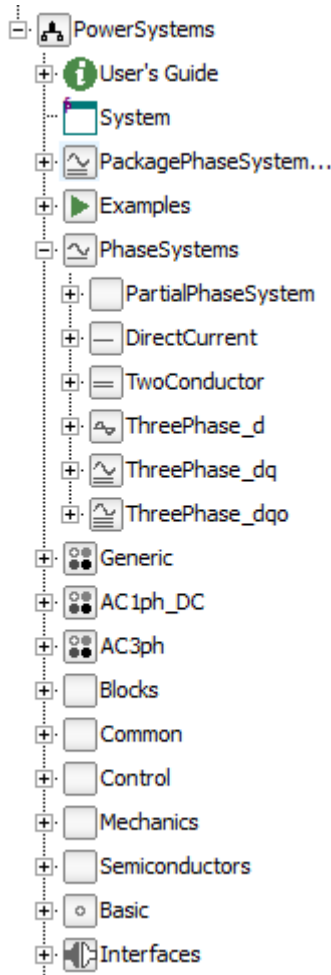

- AC systems, including steady-state, transient, and asymmetric,
- Variable frequency systems, e.g. in wind turbines or for drive control, and
- DC power systems, like HVDC

The replaceable phase systems also enable the application of one and the same library with one universal connector to different levels of detail. This starts from simple power balances and ranges through quasi-static models up to the treatment of detailed transient effects.

## 2 Library Structure and Interfaces

### 2.1 Library Structure

Figure 1 shows the package structure of the PowerSystems library.

**Figure 1: Library structure of PowerSystems**

The main packages are:

- **Examples** cover textbook power flow calculations, a demo for power/frequency control and introductory tutorials to the detailed component models;
- **PhaseSystems** defines different mathematical representations of electrical systems;
- **Generic** contains simple component models that can be used with any phase system for basic investigations;
- **AC1ph\_DC** contains detailed component models for DC and one phase AC;
- **AC3ph** contains detailed component models for three phase AC;

- **Blocks** contains signal oriented models, such as Multiplex and Transforms;
- **Control** contains special control blocks, such as Exciters or Governors;
- **Mechanics** provides TurboGroups, complementing a generator with rotor and gears;
- **Semiconductors** define required components such as Diodes and Thyristors.

### 2.2 Interfaces and PhaseSystems

The interfaces define a general power terminal.

```

connector Terminal
  replaceable package PhaseSystem;

  PhaseSystem.Voltage
    v[PhaseSystem.n];

  flow PhaseSystem.Current
    i[PhaseSystem.n];

  PhaseSystem.ReferenceAngle
    theta[PhaseSystem.m]
    if PhaseSystem.m > 0;
end Terminal;
  
```

The connector contains a replaceable PhaseSystem package making it applicable to different mathematical representations. The PhaseSystem defines:

- Number  $n$  of independent current and voltage components
- Number  $m$  of reference angles
- Types used in the connector (Voltage, Current, ReferenceAngle) so that terminals of different phase systems cannot be directly connected
- Functions
  - $j$  “operator”
  - angle and phase
  - phase quantities for voltage, current and power
  - system quantities for voltage, current and power

The vector of reference angles  $\theta[m]$  allows the definition of a rotating reference system for the description of AC systems with modal components. It is known from the Spot library that this enables the treatment of modal quantities in the time domain, covering transient and asymmetric systems as well.

The power Terminal is overdetermined with the reference angles though. This is treated with the operators `Connections.root`, `Connections.potentialRoot`, `Connections.isRoot` and `Connections.branch`. A Modelica tool needs to analyze connection graphs and eliminate redundant equations.

The following table summarizes the `PhaseSystems` that are predefined in the `PowerSystems` library:

PhaseSystem	n	m	Description
DirectCurrent	1	0	One voltage and one current component in natural coordinates
TwoConductor	2	0	Two voltage and two current components for Spot AC1ph_DC components
ThreePhase_d	1	0	One modal component for active power — like DirectCurrent, but converting voltage values to three phase
ThreePhase_dq	2	1	Two modal components for active and reactive power; one reference angle for frequency — cf. complex phasors with variable frequency
ThreePhase_dqo	3	2	Three modal components for active, reactive and dc power; two reference angles for Spot dqo components

A generic steady-state impedance model can be defined as:

```

model GenericInductiveImpedance
  replaceable package PhaseSystem =
    PackagePhaseSystem;
  function j = PhaseSystem.j;
  Terminal terminal_p(
    redeclare package PhaseSystem =
      PhaseSystem);
  Terminal terminal_n(
    redeclare package PhaseSystem =
      PhaseSystem);
  PhaseSystem.Voltage v[:] =
    terminal_p.v - terminal_n.v;
  PhaseSystem.Current i[:] =
    terminal_p.i;
  PhaseSystem.Frequency w =

```

```

    der(PhaseSystem.angle(
      terminal_p.theta));
  parameter
    Modelica.SIunits.Resistance
    R = 1 "active component";
  parameter
    Modelica.SIunits.Inductance
    L = 1/50
    "reactive component";
  equation
    v = R*i + w*L*j(i);
    zeros(PhaseSystem.n) =
      terminal_p.i + terminal_n.i;
    if PhaseSystem.m > 0 then
      terminal_p.theta =
        terminal_n.theta;
      Connections.branch(
        terminal_p.theta,
        terminal_n.theta);
    end if;
end GenericInductiveImpedance;

```

Note the use of the function `j` that generalizes complex calculations known from quasi-static AC models to arbitrary phase systems. `ThreePhase_dq` with two model components for active and reactive power defines a multiplication with the complex `j`:

```

function j
  input Real x[n];
  output Real y[n];
algorithm
  y := {-x[2], x[1]};
end j;

```

The simpler `ThreePhase_d` neglecting reactive power defines:

```

function j
  input Real x[n];
  output Real y[n];
algorithm
  y := zeros(n);
end j;

```

The more detailed `PhaseSystem_dqo` also considers a component for dc power in asymmetric systems, besides active and reactive power. It defines:

```

function j
  input Real x[n];
  output Real y[n];
algorithm
  y := cat(1, {-x[2], x[1]},
    zeros(size(x,1)-2));
end j;

```

The GenericInductiveImpedance model adapts to the selected PhaseSystem.

### 3 Component models and Examples

The PowerSystems library contains simple examples, including textbook power flow calculations, demonstration of power/frequency control, and tutorials for the modeling of power system transients.

#### 3.1 Network flow calculations

PowerSystems.Examples.Network contains examples that treat power flow with the quasi-static ThreePhase\_dq by using simple generic component models.

Figure 2 shows the Generic component models used by these examples.

Figure 2: Generic component models

The NetworkLoop example implements a simple power flow model; see Figure 3. The textbook example is taken from [4].

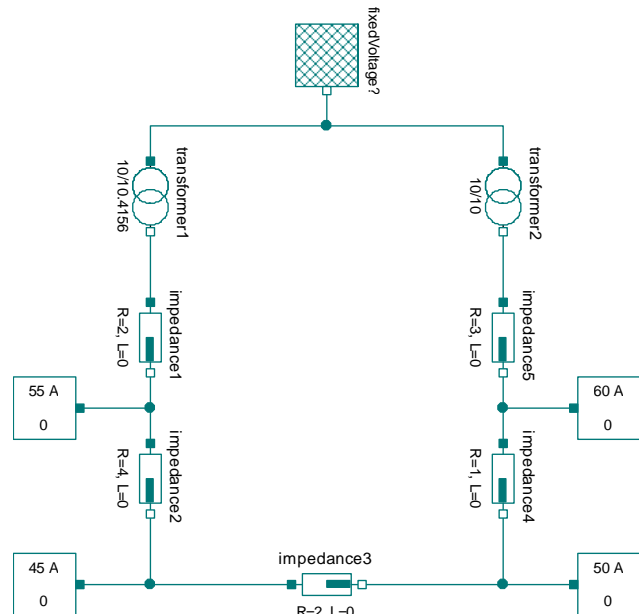

Figure 3: NetworkLoop example

The example demonstrates that the PowerSystems library enables the direct implementation of power flow models using established graphical representations. The graphical representation differs from electrical circuits as treated e.g. with the Electrical.Analog library. The FixedVoltageSource has only one terminal, as opposed to two pins in the Electrical.Analog library. Moreover there is no Ground component needed to treat loops.

#### 3.2 PowerWorld

PowerSystems.Examples.PowerWorld demonstrates the principles of power/frequency control; see Figure 4.

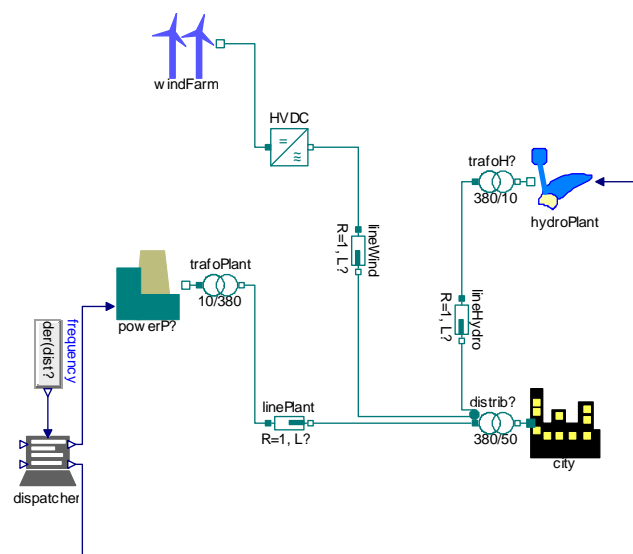

Figure 4: PowerWorld example

The example uses Generic components with the quasi-static ThreePhase\_dq because fast electrical transients and asymmetries are neglected. Rotating masses in the power plants and active power/frequency control determine the system dynamics.

Figure 5 shows simulation results covering one day of operation.

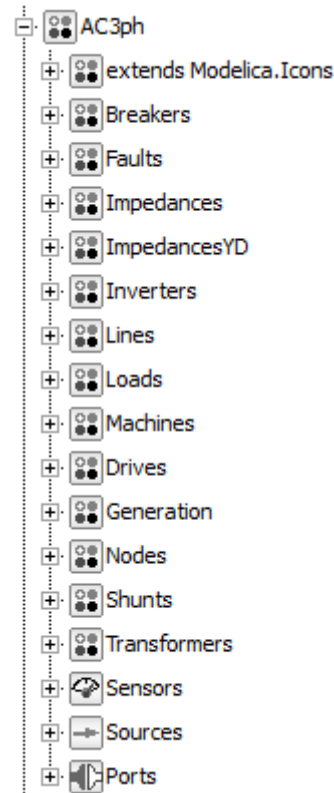

**Figure 5: Simulation results for the PowerWorld example**

The wind farm introduces disturbances into the system, caused by deviations of the actual weather from the forecast – see forecast in magenta vs. actual feed-in in green in the upper plot. A misbalance between production and consumption leads to deviations of the grid frequency from the nominal value of 50 Hz. The conventional power plant and the hydro plant accommodate for deviations with primary frequency control by means of proportional control. The remaining control error is exploited by the load dispatcher to determine the misbalance and to send out set points for secondary frequency control. This way the fast primary frequency control is relieved with the slower secondary frequency control, so that subsequent disturbances can be treated as well. The overall balance between production and consumption is maintained.

The example does not cover tertiary frequency control and intraday optimization that form further control loops on top of secondary and primary frequency control – see also the application in section 4.2 below.

### 3.3 Spot examples

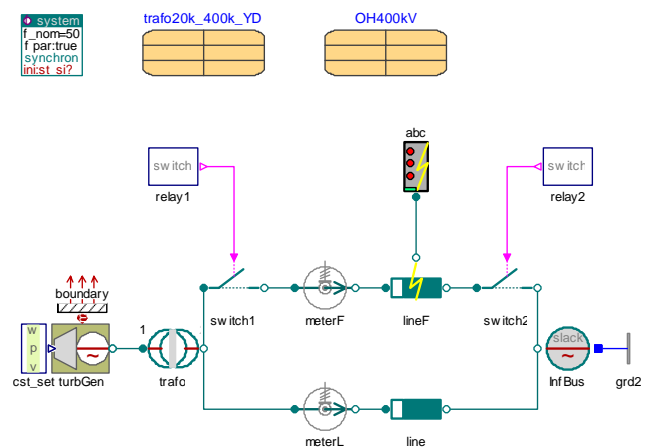

PowerSystems.Examples.Spot has been ported from the Spot library [3]. They use the components from AC1ph\_DC and AC3ph; see Figure 6.

**Figure 6: AC3ph component models**

The extensive AC3ph components range from simple impedances through special devices such as breakers up to transformers, inverters and electrical machines. Moreover they cover composed models for Drives and Generation.

The Spot examples serve as tutorials for detailed transient modeling of electrical power systems. Figure 7 shows the fault clearance by short-time line switched off as example.

**Figure 7: DoubleRXline example**

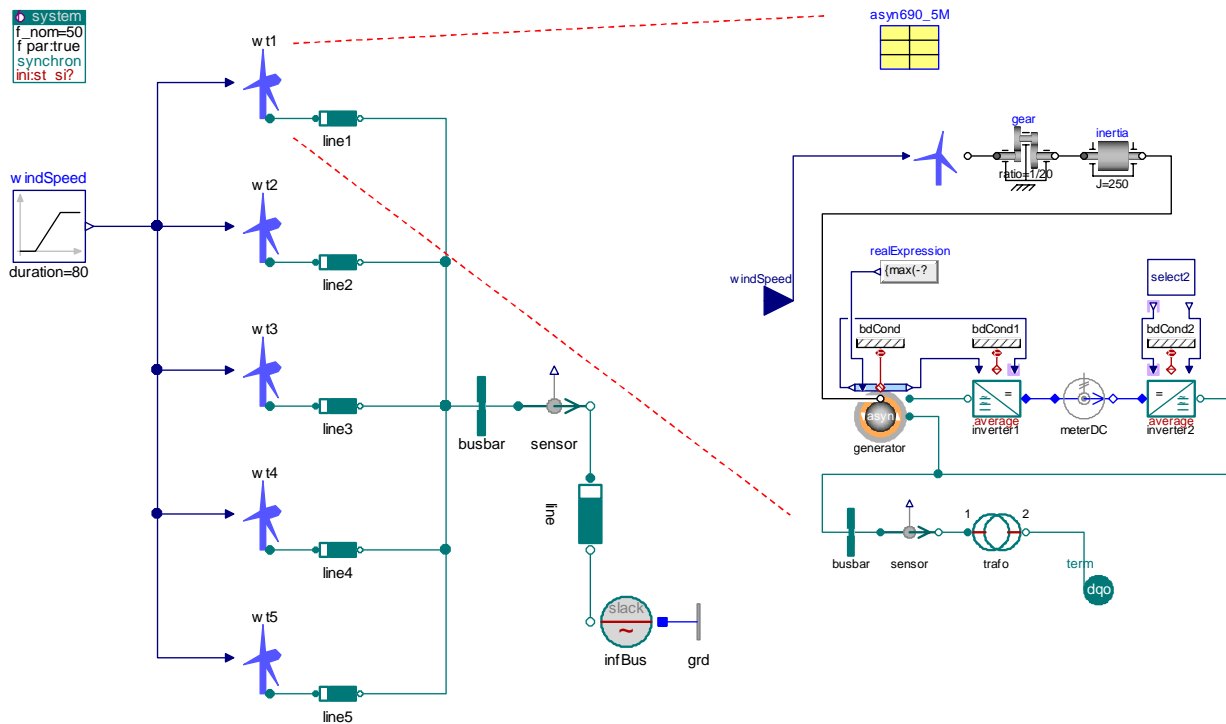

Figure 8: Wind farm model (electrical side)

## 4 Applications

### 4.1 Drive trains of wind turbines

The ITEA research project MODRIO aims for model driven online application. One application area addresses wind turbines. They are challenging because multiple physical domains need to be covered to master the overall system dynamics. The PowerSystems library has been used to implement transient models of electrical drive trains. Figure 8 shows an example with doubly fed induction generator (DFIG) on the right hand side. Multiple such wind turbine models have been assembled to a wind farm model as shown on the left hand side.

The electrical model will be integrated with a model for the mechanical side by SIMPACK.

### 4.2 Intraday optimization of municipal power

Traditional power/frequency control runs into limitations when facing large uncertainties due to increasing use of renewable energy. Intraday optimization reacts on new conditions by re-planning the power production. Such an intraday optimization was developed within the project econnect Germany for the investigation of the integration of emerging electric mobility with power generation.

The PowerSystems library has been used as basis for an optimization library. The optimization library predefines component models that contain, besides physical equations, also optimization constraints and objective terms. This way optimization programs can be implemented graphically like simulation models.

Figure 9 shows an exemplary model. The library is shown as tree on the left hand side. The intraday optimization treats a virtual power plant (VPP) consisting of multiple power generation units, such as wind, solar, hydro, as well as combined heat and power plants. Available storage capacities include heat buffers and a large battery. Moreover the exploitation of electric cars and of heat pumps as controllable consumers is investigated.

The Modelica model is translated to C code and exported as Functional Model Unit (FMU) to the ABB control system. The FMU is used a basis for a large-scale mixed integer optimization program, providing a model predictive control of the VPP. The online optimization approach is further discussed in [5].

Figure 10 shows the result of one optimization run. Dotted lines mark the original day-ahead plan. Caused by a surplus of wind production, the intraday optimization reduces the use of combined heat and power BHKW plants (green areas) until the heat buffers reach their lower limit (red areas). A battery that is installed in a parking house is charged at times when there is too much power in the grid. More details of the intraday optimization are given in [6].

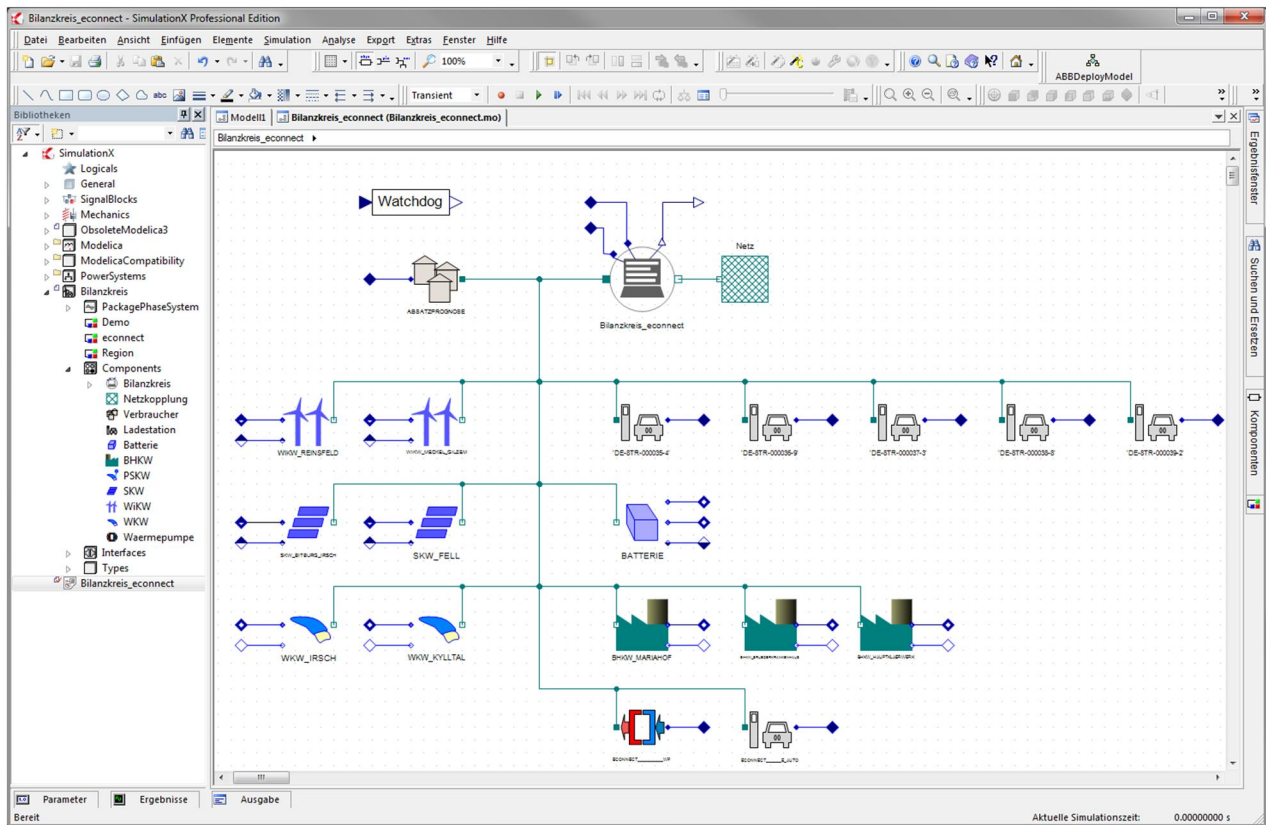

Figure 9: Optimization model for municipal power

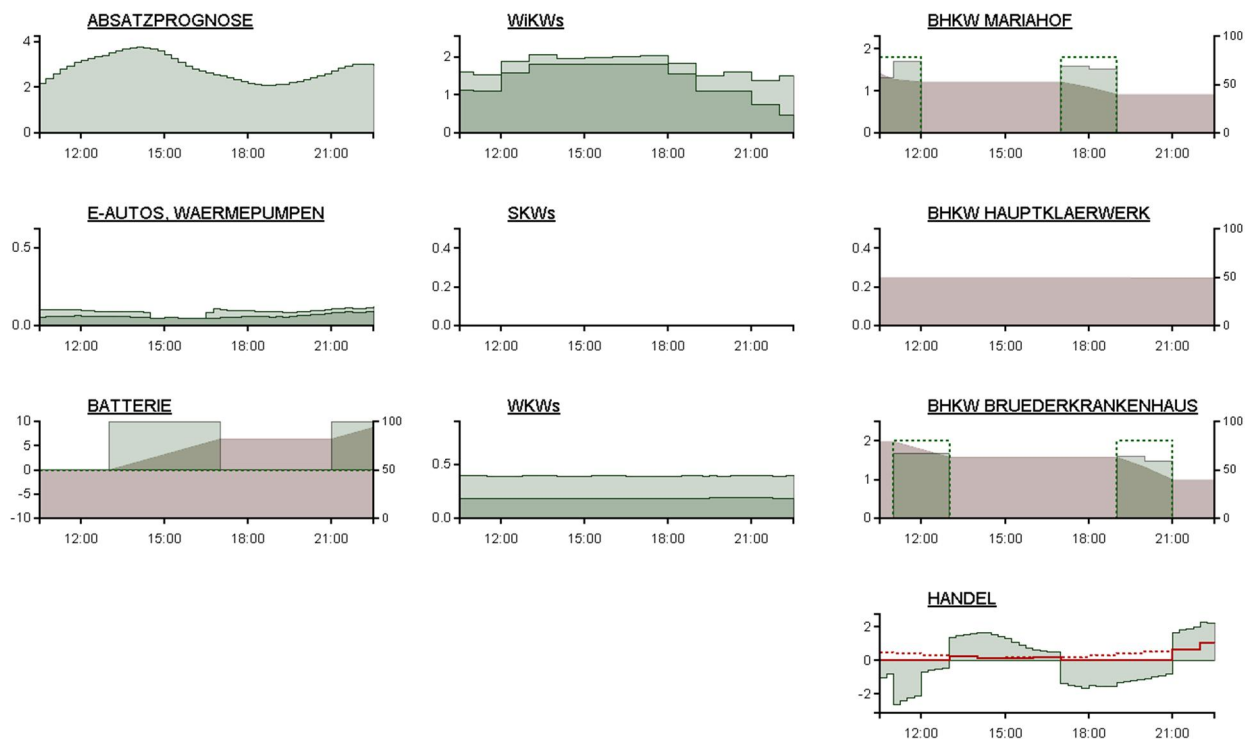

Figure 10: Exemplary intraday optimization result

## 5 Conclusions

The PowerSystems library started as a concept study for defining configurable phase systems, together with simple generic component models and universal power connectors. Later on the Spot library was integrated, so that extensive sets of detailed component models for DC and three-phase AC are available.

This way PowerSystems provides the comprehensiveness of Spot on the one hand side. Moreover, the new replaceable phase systems enable models at different level of detail, including also simple models for active power balances, besides symmetric and asymmetric AC models for active and reactive power, both steady-state and transient. A couple of examples and applications show the usefulness of the library at different levels of detail.

The PowerSystems Library is available under the Modelica license, version 2, at: <https://github.com/Modelica/PowerSystems>

Given sufficient interest by others, future work shall address the integration of the PowerSystems library or its concepts with the Modelica Standard Library.

## Acknowledgements

We thank Martin Otter who has converted the original Spot library to Modelica 3. This significantly simplified its integration with PowerSystems.

This work was supported in parts by BMBF within the ITEA2 project MODRIO (Model Driven Physical Systems Operation) – project id: ITEA 2 – 11004.

The project econnect Germany is funded by the federal ministry for economy and technology due to a decision of the federal parliament.

## Abstract

This paper presents a newly developed Power Electronic Inverter library in Modelica. The library utilises a multi-level approach with increasing model complexity at progressively higher levels. All levels are fully interchangeable so as to provide a flexible library able to be utilised for investigation at single or multiple levels of complexity. Within this interchangeable multi-level approach, there are two key attributes which are implemented into this new library. The first is the ability to include losses between the input and output of the Power Electronic Inverter. This is implemented so that the losses are included irrespective of the direction of power flow. Secondly, this library also provides the ability to trigger single or multiple open and short circuit faults within the Inverter. The library therefore provides an extremely useful tool able to compare system response under a variety of operational scenarios.

## 1 Introduction

Power Electronic Inverters convert DC electrical power to AC. They are a vital part of the modern world and are becoming increasingly common due to the electrification of modern transport systems. They are used to drive the electrical machines within electric vehicles [1] and are an essential part of electrically driven actuator systems within the More Electric Aircraft [2]. Indeed the adoption of electrically driven actuators is becoming widespread among aircraft manufacturers due to the evident benefits in terms of efficiency, weight and maintenance [3]. However, despite the high efficiency of these electrical systems and low probability of fault occurrence, it is still essential to consider the losses that do occur and the effect of fault conditions. The *Inverters*

library presented here provides the ability to include losses, analyse thermal response and introduce fault conditions into the modelling environment. It also gives the user multiple interchangeable models of the Power Electronic Inverter in order to allow analysis at multiple levels of complexity. This is a new approach as the MSL, SPOT, Smart Electric Drives and Modelon's ElectricPower libraries do not provide this flexible multi-level approach with loss and fault capability [4][5]. The *Inverters* library presented here forms part of an overall *Actuator* library developed as part of Actuation 2015 [6]. For an overview of the entire *Actuator* library please see [7]. However the purpose of this paper is to give in-depth detail on the multi-level modelling of the Power Electronic Inverter.

At first the library structure will be presented along with a definition of the multiple modelling levels. Details of the individual models will be given including both commonalities and differences. Simulation results will be shown in order to demonstrate results which can be obtained using the 5 modelling levels.

## 2 Multi-level definition

Before detailing the actual models a definition of each modelling level must be given. This is defined in line with the overall definition established by all partners within Actuation 2015 [6]. Table 1 shows the agreed definitions which are used throughout the *Actuator* library [7] and are also used within this *Inverters* library.

Level	Colour
1	Perfect
2	Linear Effects, Invertible
3	Non-Linear Effects, Invertible
4	Hard Non-Linear Effects
5	Fully Switched Models

Table 1: Modelling level definition.

In addition common colour coding was agreed for each modelling level as detailed in Table 2.

Level	Colour
1	Red
2	Blue
3	Grey
4	Green
5	Dark Yellow

Table 2: Colour coding of each modelling level.

### 3 Structure

Figure 1 shows the structure of the `Inverters` library.

Figure 1: Structure of the `Inverters` package.

The `Inverters` package provides 5 levels of complexity in line with the multi-level definitions detailed in Section 2. As can be seen from Figure 1 the package is split into the `NonSwitching` package and the `Switching` package. The `NonSwitching` package provides colour coded models for levels 1 to 4 and the `Switching` package provides the level 5 model. Each level has a corresponding example of its use. The colour and level assignment of each model is in line with the definition of the modelling levels for the overall `Actuator` library as detailed previously in Section 2. The colours for each level and the icons for `NonSwitching` and `Switching` models are extended from the `Inverters.Utilities.Icons` package.

## 4 Model Interfaces

A central feature of this `Inverters` library is that each modelling level is fully replaceable with one another. In order for each modelling level to be fully interchangeable a common interface is used for all 5 modelling levels.

The electrical interfaces adopted for the DC interface are the Modelica Standard Library (MSL) `PositivePin` and `NegativePin`. On the AC side a `PositivePlug`, is used and it is assumed that a 3 phase AC side is used. A `RealInput[3]` is used for input of the 3 phase AC voltage demands. If closed loop control is used then the `RealInput[3]` input signals should be the unmodulated outputs of the current controller. A `PartialConditionalHeatPort` is used as a thermal interface for all levels. These interfaces are defined and then extended from the package `Actuator.Electrical.Interfaces`.

## 5 Non-Switching

### 5.1 Theoretical basis

There are two assumptions which are used as the basis of creating the `NonSwitching` package of Inverter models. The first assumption is that the AC output voltage signals, which in a `Switching` Inverter would be created via Pulse Width Modulation, are ideally created with a pure fundamental frequency exactly as demanded by the control signals. As such the unmodulated voltage demand signals can be used to ideally create the electrical Inverter output voltages. Within Modelica this simply means taking the 3 phase demand `RealInput[3]` and connecting it to a MSL `SignalVoltage` model, with  $m=3$ . This forms the initial basis of the Inverter model on the AC side and is constant throughout all the Inverter models within the `NonSwitching` package. Figure 2 shows this along with the inclusion of the second assumption detailed below.

The second assumption which forms a basis of the `NonSwitching` package is the power equivalence principle. This assumes that the power input to the Inverter is equal to the power output from the Inverter. As one side of the Inverter is AC and one is DC then:

$$P_{DC} = P_{AC} \quad (1)$$

In addition as:

$$P_{DC} = I_{DC} V_{DC} \quad (2)$$

Therefore substituting (2) into (1):

$$I_{DC} V_{DC} = P_{AC} \quad (3)$$

Where  $P_{DC}$  is the Inverter DC side power,  $P_{AC}$  is the Inverter AC side power,  $I_{DC}$  is the Inverter DC side current and  $V_{DC}$  is the Inverter DC side voltage.

Now, as both the AC power and the DC voltage can be measured, this means the DC current can be calculated by:

$$I_{DC} = \frac{P_{AC}}{V_{DC}} \quad (4)$$

The AC power is measured on the AC side using a MSL PowerSensor model with  $m=3$ . The DC voltage is measured using the MSL VoltageSensor model. However only the absolute value of the DC voltage is required and so a MSL Abs model is used. The calculated DC current is output using a MSL SignalCurrent model. This structure therefore creates the Level 1 Inverter and is the basis for the Level 2, 3 and 4 Inverters. It is summarised in block form in Figure 2. No thermal response is included within Level 1 as no losses exist.

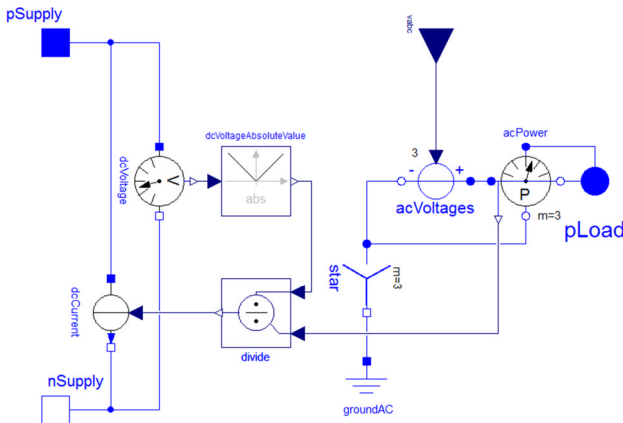

Figure 2: Basis of the Level 1 Inverter.

## 5.2 Losses

This sub-section now builds on the details given in Section 5.1 in order to create the level 2, 3 and 4 Inverter models.

To begin, it is important to note that all the Power Electronic Inverter models are fully multi-directional. As a result losses are implemented whether power flow is from the DC side to the AC

side or from the AC side to the DC side. Hence if power flow is from DC to AC the AC side power will be lower than the DC side and vice versa. This is made inherent within Levels 2, 3 and 4 by use of the MSL models shown in Figure 3. As can be seen from Figure 3 Sign is used to detect the sign of the AC power. This is then used, along with Switch and GreaterEqualThreshold, with threshold=0, in order to switch between two Constant sources. The Constant sources provide two differing values dependent on the efficiency of the Inverter and the direction of power flow as will be detailed below.

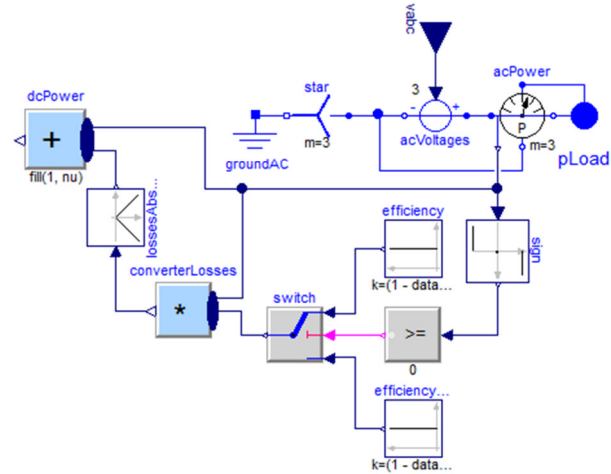

Figure 3: Basis of the Level 2 Inverter.

Irrespective of the direction of power flow, in order to calculate both the Inverter losses and the DC power the same power equivalence principle is used as detailed in Section 5.1. However, as Inverter efficiency is now included, (1) is now modified.

When power flow is from the DC side to the AC side (1) becomes:

$$\eta P_{DC} = P_{AC} \quad (5)$$

Where  $\eta$  is the efficiency of the Inverter.

When power flow is from the AC side to the DC side (1) becomes:

$$P_{DC} = \eta P_{AC} \quad (6)$$

However an important aspect of this model is that a thermal response is also given, as will be described in Section 5.3, and as such the power lost within the Inverter must be found. Therefore it is crucial to have both the power losses and the DC power in terms of the specified Inverter efficiency and measured AC power.

Efficiency is defined as:

$$\eta = \frac{P_{\text{OUTPUT}}}{P_{\text{INPUT}}} \quad (7)$$

And:

$$P_{\text{OUTPUT}} = P_{\text{INPUT}} - P_{\text{LOSSES}} \quad (8)$$

Where  $P_{\text{OUTPUT}}$  is output power,  $P_{\text{INPUT}}$  is input power and  $P_{\text{LOSSES}}$  is the power lost from the device between input and output.

Substituting (8) into (7) gives:

$$\eta = \frac{P_{\text{INPUT}} - P_{\text{LOSSES}}}{P_{\text{INPUT}}} \quad (9)$$

Making  $P_{\text{LOSSES}}$  the subject gives:

$$P_{\text{LOSSES}} = P_{\text{INPUT}}(1 - \eta) \quad (10)$$

This therefore gives power losses in terms of the input power. However using (7) and (8) the efficiency and hence power losses can also be defined in terms of the output power:

$$\eta = \frac{P_{\text{OUTPUT}}}{P_{\text{OUTPUT}} + P_{\text{LOSSES}}} \quad (11)$$

Hence in terms of  $P_{\text{LOSSES}}$ :

$$P_{\text{LOSSES}} = \frac{P_{\text{OUTPUT}}(1 - \eta)}{\eta} \quad (12)$$

Equations (10) and (12) are crucial as they define the power losses in terms of both input and output power. As a result, when power flow is from the DC to the AC side the AC side is the output and (12) gives:

$$P_{\text{LOSSES}} = \frac{(1 - \eta)}{\eta} P_{\text{AC}} \quad (13)$$

Whereas when power flow is from the AC side to the DC side then the AC side is the input and (10) gives:

$$P_{\text{LOSSES}} = (1 - \eta)P_{\text{AC}} \quad (14)$$

Within the Inverter models developed here, these two results are incredibly useful as in both cases the power losses are defined in terms of the measurable AC power and the specified efficiency. Hence, as shown in Figure 3 and described earlier, the AC power can be measured and multiplied by the coefficients shown in (13) and (14) in order to find the power lost. This is implemented using two `Constant` sources which are selected depending on the direction of power flow.

Next, the DC power must also be defined in terms of the specified efficiency and AC power. Therefore if power flow is from DC to AC then (8) becomes:

$$P_{\text{AC}} = P_{\text{DC}} - P_{\text{LOSSES}} \quad (15)$$

Substituting (13) for  $P_{\text{LOSSES}}$  and making  $P_{\text{DC}}$  the subject gives:

$$P_{\text{DC}} = P_{\text{AC}} + \frac{(1 - \eta)}{\eta} P_{\text{AC}} \quad (14)$$

Now if power flow is from AC to DC then (8) becomes:

$$P_{\text{DC}} = P_{\text{AC}} - P_{\text{LOSSES}} \quad (15)$$

Substituting (14) for  $P_{\text{LOSSES}}$  and making  $P_{\text{DC}}$  the subject gives:

$$P_{\text{DC}} = -P_{\text{AC}} + (1 - \eta)P_{\text{AC}} \quad (16)$$

If equations (14) and (16) are compared it can be seen that the only variation is the sign of the first  $P_{\text{AC}}$  term and the coefficient of the second  $P_{\text{AC}}$  term. Hence, as stated previously, both equations can be implemented within Modelica using two `Constant` sources which supply the coefficient terms and `Sign` to select between them.  $P_{\text{AC}}$  is naturally measured as positive or negative by `PowerSensor`.

Within Modelica (14) and (16) become:

$$dcPower = acPower + ((1 - data.eta)/data.eta) * acPower$$

And:

$$dcPower = acPower + (1 - data.Eta) * acPower$$

Finally, as the DC voltage can be measured, in both cases the DC current is then calculated from the DC power using (2) and implemented in Modleica as shown on the left hand side of Figure 2.

### 5.3 Efficiency

The previous sub-section showed how losses are included within the `NonSwitching Inverter` models. All losses were specified in terms of Inverter efficiency. However within the Level 2 model this efficiency is specified in a different manner to the Level 3 and 4 models.

When using the level 2 model the user is able to specify a constant efficiency for the Inverter. However if no value is specified by the user then a default value is used. This is then used under all operating conditions and is a constant throughout. The losses are not constant as they depend on the operating

conditions but the efficiency is constant. As detailed in Section 5.2 these are allowed for irrespective of the direction of power flow.

Levels 3 and 4 both use non-linear efficiency characteristics. The user is able to specify the power range of the Inverter and also the losses within the Inverter over the specified power range. A default characteristic is also given, as shown in Figure 4 below. However accurate characteristics are recommended to be added by the user if known. The default characteristics are per unit and are scaled within the model by the specified, or default, power range.

Figure 4: Default non-linear loss characteristics

These non-linear losses are implemented using CombiTable1D instead of Constant. Table 3 summarises the losses included in each level of the Inverters package. The Level 5 losses will be discussed in Section 6.

Level	Losses
1	None
2	Linear Losses
3	Non-Linear Losses
4	Non-Linear Losses
5	Conduction Losses

Table 3: Losses modelled within each level of the Inverters package.

An example system is now used to demonstrate the use of the Inverters package and show the variation in Inverter losses between levels. The Inverter is used within a system to control the speed of a Permanent Magnet Machine. The Inverter is fed from a MSL ConstantVoltage and supplies a MSL SM\_PermanentMagnet. An inner current loop is used with an outer speed control loop. Please note the controllers used are not part of the Inverters package. The overall system is shown in Figure 5.

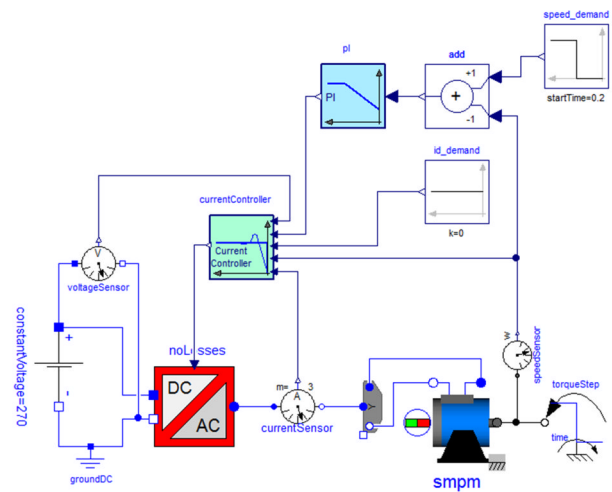

Figure 5: Example use of Inverters package.

Figure 6 shows the speed response of the system when an initial load torque is demanded at 0 seconds and a step in speed from 0 to 200 rad/s is demanded at 0.05s. A further increase in load torque is demanded at 0.14s. Figure 7 shows the 3 phase AC current response.

Figure 6: Speed response

Figure 7: 3 phase current response

Using this response the Levels 1 to 4 Inverters are simulated and the losses generated over the simulation period are compared in Figure 8.

Figure 8: Losses produced in Levels 1, 2, 3 and 4.

It can be seen from Figure 8 that the losses within the Inverter models are substantially different depending on the level of the Inverters package used. It can be seen how, in this case, the non-linear losses in Levels 3 and 4 are always higher. This is due to the Inverter operating at low to medium power. It can also be seen that the increase in losses at 0.14s is greater for the Level 2 Inverter than the Level 3 and 4 Inverters. At 0.14s the increase in losses in the Level 2 Inverter is greater as the losses are proportional to the Inverter power. However within the Level 3 and 4 Inverters the increase is less due to the non-linear loss characteristics meaning the Inverter efficiency is higher at higher power. This therefore shows how the inclusion of non-linear losses could be important. However, if accurate non-linear information is not known, operation is known to be in a linear region, or losses are not required then Level 1 or 2 Inverters can easily be used.

#### 5.4 Thermal Response

The Level 2, 3 and 4 Inverter models within the Inverters.NonSwitching package all have the same thermal implementation. As can be seen from Figure 9 a MSL PrescribedHeatFlow model is used to convert the calculated Inverter losses into heat flow. This is connected to a HeatCapacitor which represents the thermal capacitance of the Inverter switch modules. A ThermalConductor is used between the HeatCapacitor and the output PartialConditionalHeatPort in order to represent the thermal resistance between the switch module and its cooling system. A PartialCondition-

alHeatPort is used so losses can still be included if no thermal output is required.

Figure 9: Thermal implementation within Levels 2, 3 and 4 Inverter models.

The user may specify the thermal parameters for the switch modules. All the required values can be read directly from module data sheets. If no user specified value is given then default values are used.

#### 5.5 Fault

As detailed in the introduction the Inverters library presented here forms part of an overall Actuator library developed as part of Actuation 2015 [6]. A crucial aspect of the Actuator library is the inclusion of fault conditions within all the component models. In the case of the Power Electronic Inverters these are mainly included within the level 5 Switching model as no switches exist within the lower level models. However within the Level 4 Inverter a full bridge fault is possible. When triggered the Power Electronic Inverter output becomes zero. This represents a full-bridge open circuit fault or deactivation of the Inverter.

Figure 10 shows the speed response of the same system as shown in Figure 5. However in this case the Level 4 Inverter model is used and a full-bridge fault is triggered at 0.2s. Figure 11 shows the AC voltage response and Figure 12 shows the Inverter output power.

Figure 10: Faulted speed response

Figure 11: Faulted 3 phase voltage response

Figure 12: Faulted Inverter power response

It can be seen from Figures 10 to 12 that when the fault is triggered at 0.2s the Inverter output becomes 0. Therefore the output voltage and power both become 0 as shown in Figures 11 and 12. Within Figure 10 the speed response shows how, after the fault is triggered, the Permanent Magnet Machine accelerates in the negative direction due to the load torque acting as a mechanical source.

Table 4 summarises the fault conditions included in each level of the `Inverters` package. The Level 5 faults will be discussed and shown in Section 6.

Level	Faults
1	None
2	None
3	None
4	Full-Bridge
5	Single Switch, Single Phase, Multi-Phase and Full Bridge

Table 4: Fault conditions modelled within each level of the `Inverters` package.

The Failure Triggering Toolbox detailed in [7][8] is used within the models in order to trigger the required faults. A Boolean coding system is used to trigger the faults where 0 = normal operation, 1 = faulted operation. The faults can be implemented at any time instant but must be defined pre simulation.

## 6 Switching

### 6.1 Model Basis and Sub-Components

The Level 5 Inverter model within the `Inverters.Switching` package is based on the 6 switch, 3 leg topology shown in Figure 13. The switches are numbered S1 to S6 according to the order of switching. Each has a corresponding parallel diode.

Figure 13: Topology used for `Inverters.Switching` package

In order to build the Level 5 Inverter certain sub-components were needed. These are contained in `Inverters.Switching.SubComponents` and include `FaultSwitch`, `PulseWidthModulation` and `FaultInjector`.

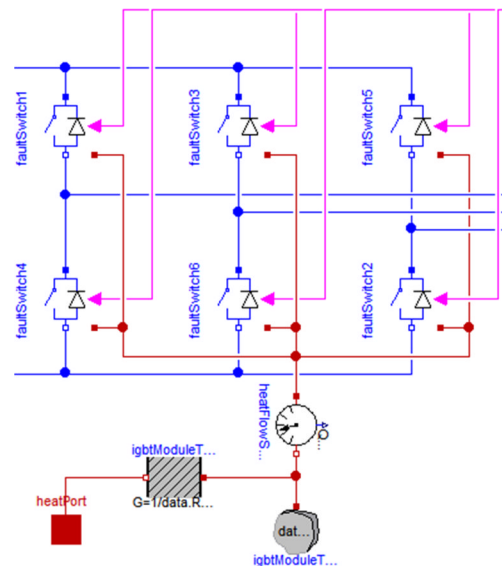

Figure 14: Basis of the Level 5 Inverter.

FaultSwitch is a model which represents the parallel switch and diode combination shown in Figure 13. Figure 14 shows how FaultSwitch is used within the Level 5 Inverter in order to create the topology shown in Figure 13.

Figure 15 shows the MSL models used within FaultSwitch. An IdealClosingSwitch MSL model is used as the main switch for power conversion. It receives a Boolean signal which dictates whether the switch is open or closed. In series with this switch is a VariableResistor. Under normal conditions the resistance of this VariableResistor is set to be a magnitude of  $10^{-6}$  smaller than the IdealClosingSwitch resistance when conducting. It therefore has negligible effect. However this VariableResistor is mainly included for use under fault conditions. As the IdealClosingSwitch resistance is very small, under short circuit conditions a very large current is obtained. In order to counteract this, the user is able to limit the short circuit current by defining a larger short circuit resistance. The VariableResistor is therefore used to introduce this larger resistance under fault conditions. A BooleanToReal MSL model is used as an input to the VariableResistor. This controls the resistance value as it receives a Boolean control signal which is false under normal operation and true under faulted operation. This does mean that the resistance also increases during an open circuit fault; however this has negligible effect due to the open circuit. The Boolean control signal comes from another Inverters.Switching sub-component named FaultInjector which will be detailed later in this section.

In parallel with the IdealClosingSwitch is an IdealDiode. The diode is uncontrolled and has default parameters, although these can also be specified by the user. This diode is also in series with the VariableResistor detailed above. As a result the increased resistance during short circuits, as detailed above, also affects the current path through the diode. During open circuit faults the combination of the diode and increased resistance provides a path for the release of otherwise trapped energy. If both paths were instantaneously open circuited then an extremely large voltage spike would be produced due to trapped energy. In a practical system this would result in sparks as the air would conduct under high voltage. However, in order to avoid these numerical spikes in this model the diode is allowed to briefly conduct.

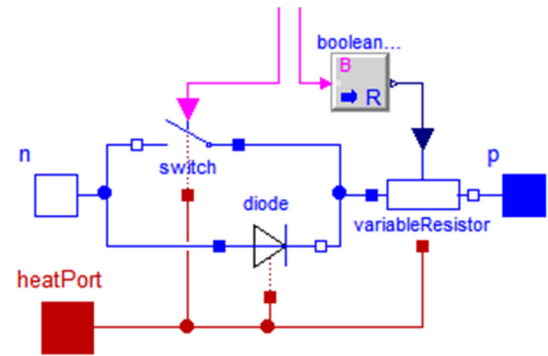

Figure 15: Inverters.Switching.Sub-Components.FaultSwitch

The PulseWidthModulation sub-component implements sine-triangle Pulse Width Modulation in order to create the 6 required switching signals. The user is able to specify the switching frequency and also the modulation index. In order to make all 5 modelling levels interchangeable the voltage demand signals which are input to the Level 5 Inverter are required to be un-modulated as was the case for Levels 1 to 4.

Finally, the FaultInjector sub-component is simply used to override the Pulse Width Modulated switching signals when a fault is triggered by the user. Under normal operation the switching signals are fed through the FaultInjector unchanged however when a fault is triggered the Pulse Width Modulated switching signals are blocked and the relevant fault state is output to the relevant switches. In addition the FaultInjector sub-component also generates the Boolean control signal which dictates the resistance of the VariableResistor contained within FaultSwitch. Boolean logic is used to create the relevant signal required to increase the resistance of the VariableResistor during faulted operation.

The Failure Triggering Toolbox detailed in [7][8] is used within FaultInjector in order to trigger the required faults. An Integer coding system is used to trigger the faults where 0 = normal operation, 1 = short circuit and 2 = open circuit. The faults can be implemented at any time instant but must be defined pre simulation.

## 6.2 Faults

Figures 16 to 21 show the effect of introducing faults within the level 5 Inverter. The same example system, speed demand and load torque is used as shown in Figure 5 and described in Section 5.3 except for the use of the Level 5 Inverter.

Figure 16: Speed response with a single phase open circuit fault at 0.2s

Figure 17: Current response with a single phase open circuit fault at 0.2s

Figures 16 and 17 show the effect of introducing a single phase fault. It can be seen that after the fault occurs the speed demand is still roughly maintained but with a lot of ripple and the faulted phase current falls to 0. The small current on the faulted phase is due to the dissipation of trapped energy as explained in Section 6.1.

Figure 18: Voltage over FaultSwitch1 with a short circuit fault at 0.2s

Figure 19: Current through FaultSwitch1 with a short circuit fault at 0.2s

Figures 18 and 19 show the effect of a single switch short circuit fault. Figure 18 shows the voltage over the switch. As expected, before the fault the voltage follows the Pulse Width Modulation signals but after the fault it is shorted to 0. Figure 19 shows the current through the same switch. As detailed in Section 6.1, this is limited by the specified short circuit resistance. In this case the specified short circuit resistance is  $1\Omega$  and as  $V_{DC}$  is 270V then the short circuit current is 270A. It can be seen that during the cycles of the Pulse Width Modulation where the switch should be open it continues to operate correctly.

Figure 20 shows the current response for a full bridge open circuit. As expected all 3 phase currents fall to 0 when the fault is triggered at 0.2s. Finally, Figure 21 shows the speed response for a full bridge short circuit. As with the faulted speed response for the Level 4 Inverter, shown in Figure 10, the Permanent Magnet Machine accelerates in the negative direction after the fault is triggered due to the load torque acting as a mechanical source.

Figure 20: 3 phase current response with full-bridge open circuit fault at 0.2s

Figure 21: Speed response with short circuit at 0.2s

Overall this section has shown how there are a wide range of fault conditions which can be easily introduced and investigated using the Level 5 Inverter. This again emphasises the flexibility of the Inverters library presented here.

### 6.3 Losses

The Level 5 Switching model includes the conduction losses of the switch and when conducting. Energy losses due to switching are neglected. As can be seen from Figure 15 the FaultSwitch sub-component contains a HeatPort which outputs the heat flow generated from the switch and diode conduction losses to the Switching model. These outputs are then all connected to the inputs of a ThermalConductor and HeatCapacitor.

### 6.4 Thermal response

The Level 5 Switching model uses the MSL ThermalConductor, HeatCapacitor and PartialConditionalHeatPort as detailed for Levels 1 to 4 within Section 5.4. No PrescribedHeatFlow model is needed as the switch and diode conduction losses are already in the form of heat flow. However a HeatFlowSensor is included to give the user a numerical representation of the losses within the Level 5 Inverter.

## 7 Conclusion

This paper has presented a newly developed Power Electronic Inverter library in Modelica. This library utilises a multi-level approach which gives a high level of flexibility according to the user's needs. All levels are fully interchangeable and provide multi-directional power flow. In addition this new library gives the user the ability to include multi-directional

losses at different levels of accuracy while also providing the ability to introduce a multitude of Power Electronic Inverter fault conditions.

Overall this library is an extremely flexible multi-level tool which provides Power Electronic Inverter models that can be easily inserted, parameterised, interchanged and adapted to the user's requirements.

## 8 Future

At present the whole Actuation 2015 Actuator library, which includes this Inverters library, is in the process of experimental verification. The future availability and licensing of this library is also currently under discussion within the consortium.

# Mixed phasor and time domain modelling of AC networks with changeover management

Hakan Dogan Parildar\*, Alberto Leva<sup>†</sup>

Politecnico di Milano, Dipartimento di Elettronica, Informazione e Bioingegneria  
Via Ponzio 34/5, 20133, Milano, Italy

## Abstract

Simulation studies on AC electric networks may comprehend periods of quasi-stationary operation and rapid transients. The adoption of a phasor-based approach results in high simulation efficiency, but is limited to the first of the two situations above, while for the second, time domain models are required. For system studies where both situations have to be simulated, a modelling paradigm is thus required that can join the two approaches in all the described components, and by which the simulator of an entire network can be endowed with the capability of moving back and forth from a phasor to a time domain system description automatically, taking care of the proper re-initialisations when necessary. In this paper we propose a possible solution, and apply our ideas by presenting the first *nucleus* of a Modelica library designed along them. We also show some simulation examples to support the validity and practical convenience of the proposal.

*Keywords:* AC networks, phasor models, time domain models, efficient simulation.

## 1 Introduction

Dynamic simulation is nowadays of great importance for both the design and the operation of electric networks [5]. Indeed, the availability of reliable simulation models is often enabling for the realisation of several functionalities of “smart” grids, like those described in works such as [9].

When addressing system studies – for example, but in principle not exclusively, for control synthesis purposes – it is frequently necessary to simulate long periods of (quasi-)stationary operation, interspersed with abrupt events. These two situations allow (and in some

sense call) for different modelling paradigms, however. Stationary operation is well described by phasor models, to the advantage of simulation efficiency. Events like for example the opening of a switch, on the other hand, require time-domain modelling, which is far more intensive from the computational standpoint. An intermediate case is given by “quasi-stationary” regimes, where the phasor approach can be extended by means of the so-called “swing equation”, which (simplifying for brevity) turns the algebraic phasor framework to a dynamic one, introducing machine angles as the state variables.

Focusing on the two extreme cases above, it would be highly beneficial and desired that a network simulation model could switch back and forth between a phasor and a time domain description, possibly in an automatic manner, and requiring as small an effort as possible on the part of the analyst. Quite expectedly, a significant research effort is being spent on the matter, but nonetheless some questions are still open, especially if a strict application of the object-oriented paradigm is required—i.e., more specifically, if all the encountered modelling issues are to be managed at the level of the individual components.

In this paper, we formulate a proposal to address the problem just mentioned, and prove its viability by presenting the first *nucleus* of a Modelica library, combining time domain and phasor modelling, developed along the devised approach.

The paper is organised as follows. Section 2 briefly discusses some related work, also to motivate the presented research, while Section 3 introduces the proposed approach, focusing on the automatic changeover problem. In Section 4 the library *nucleus* is outlined, and Section 5 reports a simulation example to demonstrate the viability and usefulness of the approach. Section 7 points out and synthetically discusses some open issues, while Section 8 draws some conclusions and sketches out future research.

## 2 Literature review and motivation

The need for modelling in the context of (AC) electric networks and their management has been recognised since long time ago [6]. The introduction of renewable energies and distributed generation has then increased the interest on the matter in the last decades [10], and further impulse to the mentioned research has been coming from smart grids [8].

Nowadays, simulation models of electric networks are also often combined with those of the generators' prime movers [1] to form multi-physics, multi-scale and potentially large overall models, for which the object-oriented paradigm of Modelica is particularly suited. In such cases, however, the electric part of the model is often the bottleneck for simulation efficiency, and the reason for that is structural.

In extreme synthesis, in fact, an AC network can be modelled at three levels. The most efficient one from the computational standpoint is provided by phasors [2]: this framework allows to write an algebraic model, that however is valid only in the hypothesis of a single, constant frequency for all the network. Small fluctuations of "local" frequencies are allowed by the so-called "swing equation" formalism, see e.g. [7], the application of which leads to dynamic component models, having machine angles as state variables.

Quite intuitively, the idea of using phasor models in Modelica is not new, but to the best of the authors' knowledge, to date no attempt was made to have phasor and time domain descriptions *co-exist* at the *component* level. For example, in [3] the idea of coupling phasor-domain and "transient" models is introduced, but the connection between the two relies on causal signals, making it difficult to represent it at the individual component level, especially for what concerns the domain changeover. Another interesting paper is [4], where however no changeover to time domain is considered, and the possibilities of phasor-based modelling are exploited via a convenient use of the swing equation.

As such, even a minimal literature analysis like that reported indicates that the problem addressed herein is of both theoretical and practical interest, and that the attempted solution has some novelty characteristics.

## 3 Mixed time-domain and phasor modelling

As anticipated, phasor models in Modelica are not a novelty [3, 4], and as such, the proposals that we are

making with this paper are to be integrated in the *scenario* depicted by works like the ones just quoted.

However, this research has some specific peculiarities, a discussion on which (and the consequently proposed solution) provide the main contributions of this paper. Specifically, three aspects are herein addressed:

- creating models that contain *both* a phasor and a time domain description of a given component,
- managing the transition (changeover) between the two at the component level,
- managing the *decision* to make a changeover at the overall model level.

As can be easily guessed, the main problem in structuring the required models is to preserve object orientation, the benefits of which are apparently not to be justified here, despite some facts to be handled are not confined to a single component—most notable, in this respect, is the changeover decision.

The rest of this section, organised along the items above, presents the proposed solution and provides motivations for it, also in a view to stimulating further discussions and improvements.

### 3.1 Component-level modelling

We now consider the problem of mixing phasor and time domain descriptions in the same component model, and of managing at that level the changeover between the two.

First, suitable physical (i.e., in this case, electrical) connectors are necessary. To this end, a positive phasor and time domain pin is straightforwardly defined (we omit trivial code like the inclusion of the `Modelica.SIunits` package) as

```
connector ptPin "phasor/time positive
pin "
    Voltage Vre "V phasor , R part";
    Voltage Vim "V phasor , I part";
    Voltage v "v(t), time domain";
    flow Current Ire "I phasor , R part";
    flow Current Iim "I phasor , I part";
    flow Current i "i(t), time domain";
end ptPin;
```

Listing 1: connectors.

and a negative one is created in the same way. Then, each component has to contain the constitutive equations for both the phasor and the time domain description, and to this end, we have to distinguish between passive components and active ones—i.e., generators.

Taking the Inductor component as a representative example for the former type, and denoting by  $a$  and  $b$  its positive and negative pin, respectively, the time domain description is

$$\begin{aligned} 0 &= a.i + b.i; \\ a.v - b.v &= L * \text{der}(a.i); \end{aligned}$$

Listing 2: inductor, time domain equations.

while the phasor one reads

$$\begin{aligned} 0 &= a.Ir + b.Ir; \\ 0 &= a.Im + b.Im; \\ a.Vr - b.Vr &= (L * \text{freqHz} * 2 * \pi) \\ &\quad * \sqrt{a.Ir^2 + a.Im^2} \\ &\quad * \cos(\text{atan2}(a.Im, a.Ir) \\ &\quad \quad + \pi/2); \\ a.Vim - b.Vim &= (L * \text{freqHz} * 2 * \pi) \\ &\quad * \sqrt{a.Ir^2 + a.Im^2} \\ &\quad * \sin(\text{atan2}(a.Im, a.Ir) \\ &\quad \quad + \pi/2); \end{aligned}$$

Listing 3: inductor, phasor equations.

Finally, the code for initialising the time domain equation when needed is

```
if flag_for_reinit then
  when {TimeDom} then
    reinit(a.i,
      sqrt(pre(a.Im)^2 + pre(a.Ir)^2)
      * sin(2*pi*freqHz*time
        + atan2(pre(a.Im), pre(a.Ir)))
    end when;
end if;
```

Listing 4: inductor, time domain (re-)initialisation.

where `TimeDom` is a flag indicating that the entire model is simulated in the time domain.

Coming to generators, the relevant equations for an ideal sine voltage one are shown below.

$$\begin{aligned} 0 &= a.Ir + b.Ir; \\ 0 &= a.Im + b.Im; \\ \cos(\text{phase}) * V &= a.Vr - b.Vr \quad \text{"Re of V"}; \\ \sin(\text{phase}) * V &= a.Vim - b.Vim \quad \text{"Im of V"}; \\ 0 &= a.i + b.i; \\ \text{if TimeDom then} \\ &a.v - b.v = V * \sin(2 * \pi * \text{freqHz} * \text{time} \\ &\quad \quad \quad + \text{phase}); \\ \text{else} \\ &a.v - b.v = 0; \\ \text{end if}; \end{aligned}$$

Listing 5: sine voltage generator equations.

At the component level, changeover is thus managed by acting in a coordinated manner on passive and active components, in a view to avoiding unnecessary events and enhance simulation speed. It can be in fact noticed that when the phasor model is in use, the time domain voltage is just zeroed. This makes the state variable  $a.i$  in Listing 2 simply decay to zero, avoiding conditional equations and limiting the triggered events to the bare minimum (the transition of `TimeDom` from true to false, or *vice versa*). Of course, said decay to zero is meaningless as simulation result, which is however indicated by the value of `TimeDom`.

The only *caveat* with the proposed solution is that the currents of inductors in series – or, dually, the voltages of capacitors in parallel – may be treated by the tool at hand as a single entity. The parameter `flag_for_reinit` in Listing 4 has the purpose of avoiding inconsistencies in such cases. At present, it is the user's responsibility to ensure that in each set of inductors in series, or capacitors in parallel, one and only one has that parameter set to true. Apart from this, however, object orientation (or more specifically, the independence of a component description of how it is connected to the others) is fully preserved.

## 3.2 System-level modelling

We now move to the problem of managing the changeover between the time domain and the phasor representation at the level of the entire simulation model, i.e., of the network—in synthesis, thus, we specify how the `TimeDom` flag is handled.

Switching from phasor to time domain is generally the consequence of some abrupt event known to at least one component, like for example a closing or opening switch. It is thus assumed that in such a case, the affected component directly sets the flag to true, causing the changeover instantaneously.

A bit more difficult is conversely the reverse changeover, since to make it feasible, *all* the currents and voltages need settling to a sinusoidal regime. The decision is in this case taken on the basis of local signalling from the components, and of a unanimity verification mechanism at the system level.

### 3.2.1 Local signalling of sinusoidal regime

Also in this case, like it was for the component-level changeover management shown in Section 3.1, the main goal of model design is to avoid unnecessary events, for efficiency reasons.

Suppose therefore that we need to detect if a certain variable  $x(t)$  – voltage or current – is “sufficiently” close to a sinusoid with frequency  $\text{freqHz}$ , assumed for the moment of zero mean for simplicity (releasing this is straightforward, see later on). Filtering  $x(t)$  through the continuous-time transfer function

$$F(s) := \frac{X_F(s)}{X(s)} = \left( \frac{1}{\pi f_o} \frac{s}{1 + \frac{s}{\pi f_o} + \frac{s^2}{(2\pi f_o)^2}} \right)^{n_F} \quad (1)$$

produces an output  $x_F(t)$  equal to the input  $x(t)$  if and only if the frequency of the latter is exactly  $f_o$ , which is apparently set to  $\text{freqHz}$ .

Figure 1: frequency detector – Bode plots of  $F(j\omega)$ .

Parameter  $n_F$  is used to enhance the attenuation of the frequency response  $F(j\omega)$  as the input frequency moves away from  $f_o$ , and a value of two (or three at most) proved enough in practice. The operation of  $F(s)$  is shown by the Bode plots of Figure 1, obtained with  $f_o = 50 \text{ Hz}$  and  $n_F = 2$ .

The output of  $F(s)$  in (1) is then used, together with its input, to form the signal

$$s(t) = \frac{1 + x_f(t)^2}{1 + x(t)^2} \quad (2)$$

which is structured so as to inherently avoid division by zero errors, and finally  $s(t)$  is lowpass-filtered by the unity-gain first-order block

$$D(s) := \frac{Y(s)}{S(s)} = \frac{1}{1 + s \frac{k_f}{2\pi f_o}} \quad (3)$$

where parameter  $k_f$  is used to control the achieved smoothing (a value of ten is a good default). As a result,  $y(t)$  will signal the required condition on  $x(t)$  by taking a value very close to the unity, with small fluctuations.

Comparing the value and the time derivative of  $y^2(t)$  to suitable thresholds, where squaring the signal is to avoid the events that would be generated if its absolute value were conversely taken, is therefore a means to detect that  $x(t)$  is close enough to a sine wave with frequency  $\text{freqHz}$ .

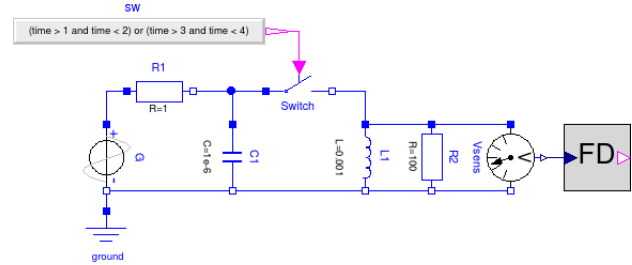

Figure 2: frequency detector test – Modelica diagram.

To show the efficacy of the proposed technique, and also its autonomy with respect to the rest of the proposed modelling paradigm, Equations (1) through (3), together with the mentioned thresholding mechanism, were turned into a `FreqDetector` block, that is used in the model of Figure 2 together with components from the Modelica.Electrical library (its use in the presented one, with the actual introduction of phasor modelling, will be illustrated later on).

Figure 3: frequency detector test – simulation results.

Figure 3 shows a sample simulation test. Detailed figures are inessential for its purpose, apparently, but as can be seen, the need for time domain modelling as caused by the switch closing and opening is detected correctly, especially for the transition toward (the possible use of) phasor mode.

Recall that the symmetric transition is in any case guaranteed by the locally originated signalling, see

Section 3.1 above. This is because the phasor to time domain transition must be *instantaneous* to preserve accuracy, while if the time to phasor domain on is delayed with respect to the time when it is acceptable, the only relevant effect is some waste of CPU time.

It is worth noticing that the 5s simulation of Figure 3 involves only 14 state events, which would apparently not be true if the possibility of switching to phasor mode were identified based on zero crossing counters, or similar methods. Note also that the proposed technique introduces some additional state variables, but these pertain to *linear, time invariant, causal* blocks *cascaded* to the physical model. The resulting simulation overhead is thus modest, and in any case much lower than that of zero-crossing or similar methods.

The default values chosen allow for a safe transition toward phasor modelling, without bounces and within a reasonable time. In the presence of an essentially constant-frequency behaviour interspersed with abrupt events that make the frequency content of the involved signals radically different from the (quasi-)stationary one, this is a good compromise between fast transition to phasor mode (which undoubtedly favours simulation efficiency) and possibly undue switching of the two modes (which conversely may be detrimental owing to re-initialisations). Also, the presented detection method is inherently normalised, since so are all the involved quantities (except times, of course). This makes the selected default values for the involved parameters valid in a wide operating range, and for an equally wide variety of network physical parameters.

To manage a possible nonzero average of  $u(t)$ , finally, the proposed filtering path is implemented as a series of transfer function blocks from the Modelica Standard Library, and signal  $s(t)$  in (2) is formed by taking the output of the first block in the place of  $u(t)$ . This ensures that the average of the signal taken as input settles to zero with a dynamics comparable to that of the transients superimposed to its steady-state sinusoidal behaviour, and at the same time preserves the exploitation of the unity-magnitude and zero-phase frequency response values at the sought frequency so as to realise the envisaged detection system.

### 3.2.2 System-level handling of TimeDom

To manage the TimeDom flag at simulation time, denote respectively with  $N_{pt}$  and  $N_{tp}$  the number of elements entitled to cause a changeover toward time domain mode (typically, switches), and that of elements the voltage across which is to be checked to approve the reverse transition.

From a conceptual standpoint this set could well be the totality of the present passive components, but for optimisation reasons the user can be allowed to introduce “frequency probes”, based on the described FreqDetector component, only where deemed necessary.

At the present state of the library development, this architectural choice is still open: most likely, however, based on the experience that is being gathered, the final solution will be to distinguish a “basic” mode, where any passive component has a detector, and an “expert” one, where the user is free to configure the mechanism at his/her best convenience.

In any case, assuming – in principle, as the implementation described in the following section is different for efficiency reasons – two boolean vectors P2T and T2P, of length  $N_{pt}$  and  $N_{tp}$  respectively, to be declared at the outermost model level, and omitting trivial details on the inner/outer manner they are managed, the following procedure for handling TimeDom is adopted.

1. The simulation starts out in time domain mode, for the safe side (possibly, in the future, unless differently specified in the “expert” mode). All the elements of P2T and T2P are conveniently initialised (at present, to false).
2. All entitled elements manage their local time domain flag based on the contained FreqDetector element, and the system-level T2P vector collects them all.
3. If at the system level time domain mode is in use, and all the elements of T2P are true, then the system switches to phasor domain mode.
4. If at the system level phasor mode is in use, any transition to true of at least one element of P2T causes a changeover to time domain mode, with the required re-initialisations.

### 3.2.3 Modelica implementation

The solution just described serves the intended purpose, and the realised one is totally equivalent from a conceptual and functional standpoint.

However, if said solution were implemented literally, some deviation from a totally object-oriented setting would be involved, since any component participating in either of the two mentioned boolean vectors, would have to contain suitable parameters to indicate

which position in said vectors pertain to it. The responsibility of setting those indices correctly would stand with the user, being possibly complex and cumbersome to manage for large models.

In addition, and most important, even if the management of the mentioned indices were somehow automated, some model connections would in this way be realised, that do not fall under a proper connector abstraction.

To overcome this relevant problem, the described solution is therefore implemented as follows. First, a *ChangeoverMgmt* connector is defined as shown below.

```
connector ChangeoverMgmt
flow Integer Ntp "# of T->P voters";
flow Real ForceP2T;
flow Real AllowT2P;
Modelica.SIunits.Frequency freqHz;
Boolean TimeDom;
Real dum "Squelch balancing warnings";
end ChangeoverMgmt;
```

Listing 6: the *ChangeoverMgmt* connector.

Each component participating in the changeover decision (i.e., each model of reactive elements or of commuting ones like switches), and also each generator, is endowed with such a connector, named in the following *C*; also, all those models take the *TimeDom* flag and the (nominal) frequency from that connector.

Reactive components (the *Inductor* model is an example) furthermore contain the code

```
C.Ntp      = -1;
C.ForceP2T = 0;
...
C.AllowT2P = if C.TimeDom and not
             FD.TimeDom
             then -1 else 0;
```

Listing 7: inductor, changeover management.

The first line reported in Listing 7 provides the *Supervisor* component, described later on and that also has a *ChangeoverMgmt* connector to which those of all network elements are connected, with the number of those elements that vote for the time domain to phasor mode transition.

The second line means that the component, given its role, is not entitled to force a transition from phasor to time domain model.

The last reported line, finally, casts the vote when this is required.

Models of commuting components (like switches) conversely contain the code

```
parameter Real Tsw    = 0.01;
parameter Real thrsw  = 0.01;
...
Real xsw(start=1);
...
xsw+Tsw*der(xsw) = if control
                   then 1 else 0;
C.ForceP2T      = if control
                   and xsw<1-thrsw
                   or not control
                   and xsw>thrsw
                   then -1 else 0;
```

Listing 8: inductor, changeover management.

When the control input (the switch command) commutes, the introduced dynamic variable *xsw* is used to generate a square pulse with a minimum of state events, and this is in turn used – see the last line in Listing 8 – to signal that the component intends to force a transition from phasor to time domain mode.

Finally, the *Supervisor* component is implemented as per Listing 9 below.

```
model Supervisor
parameter Frequency fo=50;
Interfaces.ChangeoverMgmt C;
Boolean P2T, T2P;
equation
C.dum      = 0;
P2T        = C.ForceP2T>0.5;
T2P        = C.AllowT2P>C.Ntp-0.5;
C.freqHz   = fo;
algorithm
when T2P and not P2T then
  C.TimeDom := false;
end when;
when P2T then
  C.TimeDom := true;
end when;
initial equation
  C.TimeDom = true;
end Supervisor;
```

Listing 9: supervisor.

The initial equation makes the simulation start in time domain, as specified in Section 3.2.2. Then, thanks to the flow connections, variables *ForceP2T* and *AllowT2P* respectively sum the forcing to time domain mode requests, and the permission for phasor mode votes. based on that, when *ForceP2T* is at least 0.5, then at least one component is forcing time domain mode.

Analogously, when `AllowT2P` exceeds the number of voters (collected in the `Ntp` connector variable) minus 0.5, then all said voters are permitting the transition toward phasor mode. Finally, the two `when` clauses in the `algorithm` section manage the `TimeDom` flag, triggering events only when necessary.

## 4 The library structure

As anticipated, the presented ideas were applied to create the first *nucleus* of a Modelica library for mixed phasor and time domain modelling of electric networks.

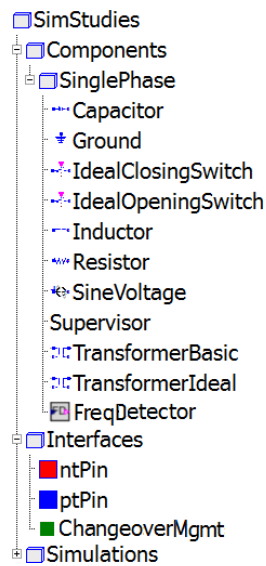

Figure 4: the library (*nucleus*) structure.

Said *nucleus* is structured as outlined in Figure 4, and to date comprises only single-phase components, connectors, and the Supervisor block to be included in the realised models so as to implement the necessary network-wide declarations, and the management of the involved variables.

Plans are of course to extend the *nucleus* to form a complete library, including more articulated components such as non ideal generators, the representation of multiphase elements, and the like. Also, care will be taken to integrate the consequent future work with (at least) the similar ones shown in the references quoted above in Section 2.

## 5 An illustrative simulation example

We now shows a simple simulation example to demonstrate the operation of the proposed modelling framework, and specifically of the changeover management.

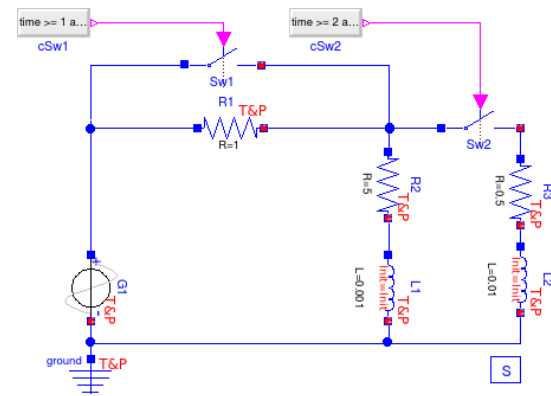

Figure 5: illustrative simulation example – the used network model.

The example refers to the small network model depicted in Figure 5. The switch Sw1, initially closed, is opened at  $t = 1\text{ s}$  and re-closed at  $t = 3\text{ s}$ . The switch Sw2, also initially closed, is cycled at  $t = 2\text{ s}$  and  $t = 4\text{ s}$ . The simulation run duration is  $5\text{ s}$ .

Figure 6: illustrative simulation example –  $y$  signals in the frequency detectors of the two inductors.

Figure 6 shows the  $y(t)$  variables – see (3) – in the frequency detectors of the two inductors. Recall that those variables are meant to indicate, by assuming a nearly constant unity value, the settling of the locally measured frequency to `freqHz` (here set to  $50\text{ Hz}$ ). As can be seen, the expected effect is obtained, and the normalised nature of the involved signals produces comparable transients also in the presence of different values for the components’ electric parameters.

Figure 7: illustrative simulation example – boolean flags.

In Figure 7, the relevant boolean flags at the system level are instead represented. The changeover mecha-

nism catches the switch events, passing to time domain instantaneously, while the time domain periods are not equal, correctly depending on the transient behaviour of the monitored electric variables.

Figure 8: illustrative simulation example – forcing time domain on the part of a switch.

Figure 8 illustrates how a commuting component forces the transition to time domain mode by means of `xsd`, and the role of the threshold and the time constant of its dynamics in determining the width of the generated pulse. Note that the rising edge of that pulse is structurally synchronous to the switch command, which is consistent with the defined specifications.

Figure 9: illustrative simulation example – current in R3, time domain representation.

Figure 10: illustrative simulation example – current in R3, phasor representation.

Figures 9 and 10 show the behaviour of the current flowing through resistor R3, viewed respectively in the time domain and as a phasor (for which the real and the imaginary part are plotted). Notice that when the simulation switches back to phasor mode after a period in time domain mode triggered by a switch event,

the time domain signal has actually settled back to a sinusoidal behaviour, making the changeover correct.

Figure 11: illustrative simulation example – current in R3, changeover detail.

Finally, Figure 11 demonstrates the changeover and re-initialisation mechanism, comparing the phasor and time domain representations for the current through R3 with a reference obtained by forcing the simulation to take place entirely in the time domain. Observe the (re-)initialisation of the time domain representation of the shown variable, triggered instantaneously by the changeover to time domain mode. Note also how the time domain representation of the same variable settles to zero after the changeover to phasor mode occurs, allowing the solver to exploit variable-step capabilities to the advantage of efficiency. As can be verified, then, taking the time or phasor domain signals as the valid ones depending on `TimeDom`, conveys all the required information.

## 6 A simulation example on efficiency

Although on this matter work is still in progress, we report an example showing the simulation efficiency gained with the proposed approach.

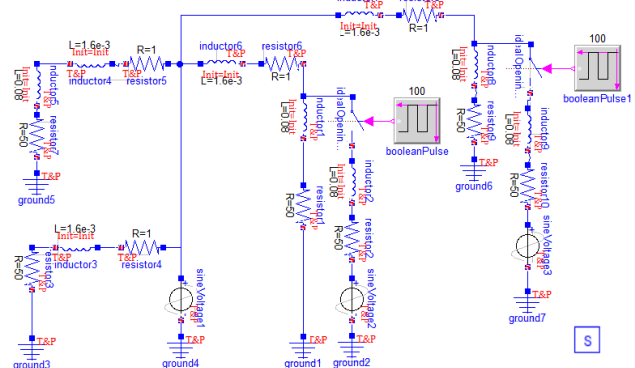

Figure 12: simulation example on efficiency – the used network model.

The example refers to the network model depicted

in Figure 12, apparently more complex than that of Figure 5 above. The network was assembled with components from the presented library, and a reference model for it was created with the equivalents from the Modelica Standard Library, limiting of course the scope to time domain modelling. Various simulations were then performed with a duration of  $10^4$  seconds, cycling the switches at regular intervals for a variable number of times.

Cycles	CPU time	Steps	F-evals	J-evals
800	161	26276873	52580944	16847
600	155	26038476	52097092	12594
400	164	26036633	52086819	8404
200	161	26103648	52214194	4259
100	160	26177418	52358292	2131
80	168	26095949	52194637	1699
40	162	26126749	52254882	853

Table 1: simulation example on efficiency – results with the Modelica Standard Library.

Cycles	CPU time	Steps	F-evals	J-evals	Events
800	134.00	1717702	5968550	759422	59257
600	97.60	1246309	4293129	538653	42139
400	67.80	857706	2980426	379132	29580
200	33.70	429941	1493272	189871	14758
100	16.90	215300	747528	95007	7424
80	13.90	173998	605417	77192	6008
40	7.12	90491	316665	40846	3207

Table 2: simulation example on efficiency – results with the proposed models.

Table 1 shows the results obtained with the Modelica Standard Library. The first column reports the number of switch cycles in the simulation, while the others contain the typical computational load statistics. Table 2 conversely shows the results achieved with the proposed models, and has a further column that reports the number of generated state events (that apparently is zero in the previous case).

Figure 13: simulation example on efficiency – CPU time percent reduction versus switch cycles.

As can be seen, the efficiency improvement is quite evident in terms of CPU time, for which the gain is represented graphically in Figure 13, number of steps and F-evaluations, although (owing most likely to the numerous re-initialisation) there is quite an increase of the Jacobian evaluations.

## 7 Open issues

As stated right from the introduction, the work presented in this paper is still in progress. We have reached sufficient certainties on the viability of the approach, with particular reference to the possibility of managing the representation changeover within a solid object-oriented setting, and without triggering undue event hauls. However, more than one relevant issue stands still open, and this section is devoted to a brief overview on them.

A first point concerns the quantification of the obtained advantages. Here some figures referring to efficiency were given, but no doubt, more extensive efficiency assessment campaigns are in order, and to this end, testing is underway with larger models. At a first glance, the impression we are getting is that the number of simulation steps reduces more or less proportionally to the fraction of the overall simulation run that can be done with phasors, which is in reasonable accordance with intuition. On the other hand, the number of Jacobian evaluation exhibits more peculiar behaviours, on which deeper investigations are also to be performed. Also, it is advisable that future studies address possible interactions with the solution algorithm, of the variable-step type for apparent reasons: at present, in fact, to date all the tests were done with DASSL only.

A second point concerns the parameters involved in the changeover management machinery. Despite the use of normalised signals has proven effective, in fact, we still observe some residual effects of the threshold values, on which further studies are consequently in order. In particular, it would be useful to somehow relate said thresholds, and also the value of the time constant for the dynamics of *xsd*, to the desired tradeoff between accuracy and efficiency improvement, quantified (for example) on the basis of the additional time spent simulating in time domain mode beyond necessary.

Moving from efficiency to model manipulation and structuring issues, a first point concerns the re-initialisation flags. At present these are to be managed by the user, but apparently could be set automati-

cally if the tool manipulation chain were somehow instructed to recognise and treat series/parallel connections. In principle, leaving the flag responsibility to the user does not seem a big problem, unless when dealing with large models where connections are changed frequently—not too realistic a case. Nonetheless, also on this point further research is advisable.

A more relevant issue is relative to the use and abstraction of non-physical connectors like the *ChangeoverMgmt* one. Here, the quest for efficiency in fact led to somehow abuse flow variables (by the way, the authors would like to thank the colleagues Francesco Casella and Victorino Sanz for ideas and useful suggestions in this respect). However, with the mechanism here adopted, more articulated voting mechanisms than the realised ones, would be cumbersome and possibly impossible to implement. In contexts like that addressed herein such mechanisms may not be necessary, but the experience reported in this work suggests that some way to tailor the connector semantics would be highly desirable—a small suggestion for discussions on future versions of the language.

Finally, although this is undoubtedly simpler and less important from a conceptual point of view, some post-processing tool would be needed that uses the produced results (phasors and time domain variables, together with *TimeDom* to say which one is significant at which time instant) to reproduce and present all the simulated quantities entirely in the time domain, for the user convenience.

## 8 Conclusions and future work

The problem of creating models of AC networks joining the phasor and the time domain approach, and switching from one another automatically during a simulation run, was addressed. A solution was proposed, having some peculiar features in particular as for the changeover mechanism, and motivations for the adopted choices were provided. The approach was put to work by creating the first *nucleus* of a Modelica library, and a simulation example – referring to a very simple case given the purpose of this paper – was shown to back up the viability and usefulness of the proposal.

Future work will be essentially aimed at tackling the issues pointed out in Section 7. In addition, the integration with models for the process sections of generators (typically, their prime movers) will be addressed, in a view to better exploit the efficiency improvements yielded by the proposed approach. Finally, given the

interest on the considered modelling and simulation domain, the authors hope that this proposal can stimulate discussions, further ideas, and collaborations.

## Abstract

To manage complexity, modern programming languages use organizational units to group code related by some common purpose. Depending on the programming language, these units might be called libraries, packages or modules. But they all attempt to encapsulate functionality to promote modular code and reusability. For the remainder of this paper, we will simply refer to these organizational units as *packages* (as they are called in Modelica).

Also common to many modern programming languages are tools to manage these packages. These tools are generally called *package managers* and they allow developers to quickly “fetch” any packages they may need for a given project. The main functions of package managers are to allow developers to search, install, update and uninstall packages with a simple command-line or graphical interface. In the Java world, the most common package manager is maven. For Python, tools like `easy_install`[1] and `pip`[2] are used for managing packages. For client-side web development, bower is used. For server-side JavaScript, the tool of choice is npm[3]. For compiled languages, these package managers often include some additional build functionality as well.

This paper introduces *impact*, a package manager for Modelica. Using *impact*, Modelica users and developers can quickly search for, install and update Modelica libraries. In this paper, we will discuss the functionality provided by *impact*. In addition, we will discuss how the functionality was implemented. As part of this we will discuss the importance of collaborative platforms, like GitHub[4] in our case, for providing a means for collecting, curating and distributing packages within a community of developers.

The *impact* package manager is provided to the Modelica community as a free, open-source tool.

Furthermore, the protocols involved are all documented and we encourage tool vendors to integrate them into their own tools so they can provide the same searching, updating and installation capabilities that the command-line tool provides.

**Keywords:** *Modelica, package manager, GitHub, dependency management, Python*

## 1 Introduction

It is increasingly the case that the adoption of new technologies hinges on automating away the tedious tasks required to learn and adopt these new technologies. For programming languages or frameworks, this means streamlining the process by which libraries can be found and installed.

For nearly all modern languages, this issue of “package management” has reached the point where it is almost an element of language design. The Java world has the maven tool, Scala has sbt, Node.js has npm and the Go language includes built-in support for package management via its the command line go compiler.

In the Modelica world, this issue has been largely overlooked. Although there have been proposals for formats to list network accessible libraries, these efforts have remained mere proposals without any concrete functionality. The *impact* project was inspired by the Bower[5] project’s approach. This lightweight, git-centric approach (discussed in Section 3) turned out to be relatively straightforward to implement and provides functionality otherwise unavailable in the Modelica world.

The goal of the *impact* project is to provide the same basic package management features found in most package managers. These features will be dis-

cussed in detail in subsequent sections of this paper (see Section 2). Our goal is to lower the barrier for users to find, install and update libraries. At the same time, we expect that the `impact` tool itself will be just as easy to install as the libraries it supports.

The contribution of the `impact` project is making installation of Modelica packages as easy as possible. There are actually three important aspects in our approach. The first aspect is the one most apparent to the user, a command-line interface that can be used to easily install not just a given Modelica library, but **also its dependencies**. However, such a command line tool must rely on the second aspect which is the availability of a centrally served, up to date index of packages. The final aspect is making it easy for library developers **to publish** their libraries in such a way that they are available to other Modelica users through the `impact` package manager. Each of these aspects will be discussed as part of this paper.

It is worth noting that while `impact` can handle dependences, it does not solve some of the problems currently inherent in Modelica. At the moment, dependencies between packages are described by individual versions. The result is that these dependencies can create brittle chains which are not always possible to satisfy. The logic for unconverging dependencies in `impact` is very simple. It merely identifies any dependencies explicitly listed by the library and then attempts to find that version of those packages within the `impact` package index. Hopefully the Modelica annotations to express dependencies will be refined to support a richer set of relationships. If so, the logic used by `impact` to identify and install these dependencies can be extended to support this improved expressiveness.

## 2 Command Line Interface

### 2.1 Installation of `impact`

The `impact` tool is available from “PyPI”[6] and can be installed by running either

```
$ pip install impact
```

or

```
$ easy_install impact
```

As an alternative one can also download the sources from <https://github.com/xogeny/impact> or <https://pypi.python.org/pypi/impact>, unpack and run

```
$ python setup.py install
```

in order to install it.

### 2.2 Searching

Searching for libraries is done by executing:

```
$ impact search <search term>
```

This will print a list of all package whose names and/or description strings contain the “<search term>”. The returned list also contains the URL where the Modelica package is hosted.

The output can also be made more verbose with:

```
$ impact search -v <search term>
```

which, in addition, will return the description string and the available versions.

### 2.3 Installing packages

Once a package of interest is found using `search`, it can be installed by executing:

```
$ impact install <package name>
```

This will then fetch not only the package itself and extract it in a configurable target directory but **it will also fetch the dependencies of the packages** as long as those are available to `impact`.

If several versions of a package are available, `impact` will choose the latest one. If this is not desirable then one can also specify the version explicitly. For example, in order to install Modelica version 2.2.2 one would execute the command:

```
$ impact install Modelica#2.2.2
```

Just like for the `search` sub-command there is also a verbose switch “-v” available for `install` which will give information on what versions are available, which version is going to be installed, what the dependencies are and where the version will be downloaded from.

In addition there is also a “[`-dry-run|-d`]” option available which does not download or extract any files but will simply report what impact *would* do. Users will generally use the “dry-run” option in combination with the “verbose” option.

### 3 Candidate Packages

The question that might arise now is, how does impact know what packages and which versions of those packages are available.

#### 3.1 Making packages visible

The Modelica Association (MA) has always maintained a list of available Modelica libraries on their website under <https://modelica.org/libraries>. Initially, the list was a static web page which listed the different packages and their latest version as submitted to the webmasters of the MA. Keeping the list of packages up-to-date was a manual job for both the website maintainers and package developers.

In spring 2013, all the free packages listed on <https://modelica.org/libraries> were moved to individual repositories on GitHub. Third-party packages can be found under <https://github.com/modelica-3rdparty> and packages by the MA under <https://github.com/modelica>. This had the following benefits:

- Package developers can access their package repository directly without having to involve the webmasters of the MA thus submitting updates any time.
- All packages now have an individual issue tracker and version control service in place.
- The webmasters of the MA can now collect the latest information on all the packages automatically in order to generate an up-to-date list-

ing on <https://modelica.org/libraries> (more on this later in Section 3.3).

#### 3.2 Semantic versioning

One thing that is important when trying to build up a package manager that can also handle version dependencies is the need for a proper approach to version numbering.

We decided to base our package manager on a system called Semantic Versioning[7]. As a result, package developers are strongly encouraged to use semantic versioning so that they are compatible with impact. This has the additional benefit of being a well-documented and logical approach.

Semantic versioning has the simple rule of:

*Given a version number MAJOR.MINOR.PATCH, increment the:*

1. *MAJOR version when you make incompatible API changes,*
2. *MINOR version when you add functionality in a backwards-compatible manner, and*
3. *PATCH version when you make backwards-compatible bug fixes.*

In addition, pre-releases (*e.g.*, beta releases, release candidates) and build metadata (*e.g.*, version control hashes) are also taken care of in this system, details can be found in the manual page[7].

#### 3.3 GitHub API

Having all packages available as GitHub repositories means that we can use the *GitHub API v3*[8] in order to collect data about those packages. All API access is over HTTPS, and accessed from the `api.github.com` domain. All data is sent and received as JSON[9].

For example if one visits: <https://api.github.com/users/modelica/repos> a verbose list containing a series of information of all repositories that exist under the user `modelica` is returned in JSON format. This includes also a new API-url for retrieving the tags of a specific repository. For example, by visiting <https://api.github.com/repos/modelica/Modelica/tags> we get a list of

all tags for the Modelica Standard Library repository including download links for a zipped version of the tagged source code.

As mentioned before, all data is returned as JSON according to a proper schema. This makes it easy to pull out all the information we need. Initially, this information was used to generate an up-to-date listing of all MA and third-party packages to be displayed on <https://modelica.org/libraries> but we also noticed quite quickly the possibilities such an API opens up. It was offering the very information we needed in order to build a catalog of available packages including the different tagged versions for download.

### 3.4 GitHub only?

The mechanism described so far seems to depend a lot on GitHub's API. So one might wonder is there a danger of locking us to GitHub.

The answer is actually no. We chose GitHub just as **one** possible data source. It is possible to enhance impact with other "connectors" to other existing package hosting solutions (private or public). As long as the schema is known to impact it can then pull its data from basically all possible places. For example, it would also be possible to use the API of the GitLab project[10] to extract the same information.

## 4 Package Index

Package information is maintained in an index file. This index file is also generated by impact but the process of building an index is not normally used by the user or tool vendors so all discussion about the creation of index files is presented later in Section 5. The index file is stored in JSON format and has the following structure:

```
{
  "<LibraryName>": {
    "homepage": "<URL>",
    "description": "<description string>",
    "versions": [
      "<version number>": {
        "version": "<version number>",
        "major": <major version number>,
        "minor": <minor version number>,

```

```
      "patch": <patch version number>,
      "tarball_url": "<URL to tarball>",
      "zipball_url": "<URL to zipball>",
      "path": "<path to library>",
      "dependencies": [
        {"name": "<DepLibName1>",
         "version": "<version string>"},
        {"name": "<DepLibName2>",
         "version": "<version string>"},
        ...
      ]
    }
    ...
  ]
}
```

All quantities listed within angle brackets, `<...>`, are library specific details. The `<LibraryName>` is the name of the package in Modelica. Generally speaking, all version numbers follow the semantic versioning approach. However, since not all Modelica libraries currently follow semantic version conventions, indices can include semantic duplicates (*e.g.*, 1.0 and 1.0.0) which reference the same underlying version. Therefore, any non-semantic conforming versions (*e.g.*, 1.0) will act as "redirects" to the semantic version (*e.g.*, 1.0.0).

The homepage field is a URL to a web site that contains additional information about the library. The zipball\_url and tarball\_url fields point to archives that can be downloaded, in the zip and tar formats, respectively. The dependencies field lists all the library's dependencies. These are the libraries that will also be installed when installing the specified library version they are listed under. The path field specifies the name of the directory or file representing the Modelica library within the specified archive.

Note, we have not currently defined a schema for this format. To promote interoperability we recognize that a formal schema would be the next logical step. We have added the creation of a JSON schema for the index file format to our list of next steps to promote interoperability with other implementations. Our hope is that such a schema would further encourage tool vendors to support this format as a means of publishing information about available Modelica libraries.

The Modelica Association index of publicly available libraries can be found at [https://impact.modelica.org/impact\\_data.json](https://impact.modelica.org/impact_data.json).

## 5 Private Packages

### 5.1 Using Private Indices

As mentioned in Section 4, there will be a package index hosted on `modelica.org` that lists any packages connected to special Modelica related GitHub accounts. This provides a means for library developers to quickly add their libraries to the set of libraries that are publicly indexed.

However, we recognize that many users will depend on libraries that cannot be hosted publicly. At the same time, we would like for those users to be able to benefit from the same kind of package management features for finding and installing their privately hosted libraries.

For this reason, users can create a special configuration file that lists the indices to be searched. By default, `impact` will use only the index hosted on `modelica.org`. But through custom configurations, users can specify any collection of indices (public or private) they wish to use.

To specify an alternative list of indices, a user would simply edit their user configuration file and add the following text:

```
[Impact]
indices=<url1>,<url2>
```

where the value of `indices` is a list of URLs pointing to index files. The default value for the `indices` variable is `https://impact.modelica.org/impact_data.json`. In cases where private index are files used, the URLs for private index files should be listed first and the URL to the index file hosted on `modelica.org` should be last.

Note, the location of the user's configuration file will depend on the platform they are using. Information about the location of the configuration file and current settings is generated by the following command:

```
$ impact info
```

### 5.2 Generating Private Indices

In order for users to include a private index file in the list of indices to be searched (as discussed 5.1), it is necessary to also have the capability to easily generate such private indices. This functionality is also available using the `impact` command line although we did not discuss it previously because it is not functionality that a typical user would require.

To generate an index file, the following `impact` command line syntax should be used:

```
$ impact refresh <source1> \
    <source2> ... <ourcen> \
    -o <output file>
```

where each source is a URL that encodes information about a potential source. For example, the default sources are `github://modelica-3rdparty/*` and `github://modelica/*` (in other words, all repositories belonging to the GitHub user `modelica-3rdparty` and all repositories belonging to the GitHub user `modelica`, respectively). Note that later sources have a higher priority than earlier sources. Also, at the moment the only types of repositories supported are GitHub repositories although by using a URL based approach it is easy to extend the possibilities to include Git, Subversion or other types of repositories as long as the information required for the index file is available.

The output file generated from this command should then be made accessible to users so they can incorporate it into the set of indices they search (see Section 5.1 for more details).

## 6 Source Code and Licensing

The `impact` project started off as a simple script, then a gist and eventually a complete repository. The repository for the source code is hosted on GitHub at `https://github.com/xogeny/impact`. Potential contributors are invited to fork the repository and add more functionality. Contributions to improve `impact` are very welcome.

The software is distributed under an MIT license. As such, there are no significant restrictions on using

the code in open-source, closed-source or commercial projects. In fact, we welcome vendor support and adoption. In addition to making the complete source code for the package manager available and documenting the functionality in this (freely downloadable) paper, we are also making the index data freely available from the `modelica.org` domain. We hope that all these measures will lead to the highest possible chance of adoption.

## 7 Conclusion

Inspired by the approach taken in Bower, we've created `impact`, a package manager for the Modelica eco-system. Like Bower, this approach is relatively light and relies heavily on the GitHub API to aggregate and index publicly available libraries. Also like Bower, our approach relies on semantic versioning, a widely adopted approach for associating concrete meaning to the various elements of a version. We use these meanings to help validate and organize the tags associated with Modelica libraries.

The `impact` tool also provides one of the key elements of a package manager, the ability to automatically pull in dependencies during installation. With this feature, users can list the libraries they directly depend on and `impact` will automatically install any additional dependencies. The dependency information is constructed automatically from the `version` annotation already present in Modelica libraries.

The index of publicly available libraries is hosted on `modelica.org`. But `impact` can also be used to index and install private libraries as well. All `impact` functionality (installing, searching, *etc.*) is available for both public and private libraries.

# MoUnit — A Framework for Automatic Modelica Model Testing

Roland Samlaus<sup>1</sup> Mareike Strach<sup>1</sup> Claudio Hillmann<sup>1</sup> Peter Fritzson<sup>2</sup>

Fraunhofer IWES, Turbine Simulation, Software Development, and Aerodynamics<sup>1</sup>  
Department of Computer and Information Science Linköping University<sup>2</sup>

## Abstract

A vital part in development of physical models, i.e., mathematical models of physical system behavior, is testing whether the simulation results match the developer's expectations and physical laws. Creation and automatic execution of tests need to be easy to be accepted by the user. Currently, testing is mostly performed manually by regression testing and investigation of result plots. Furthermore, comparisons between different tools can be cumbersome due to different output formats. In this paper, the test framework MoUnit is introduced for automatic testing of Modelica models through unit testing. MoUnit allows comparison of Modelica simulation results with reference data, where both reference data and simulation results can originate from different simulation tools and/or Modelica compilers. The presented test framework MoUnit brings the widespread approach of unit testing from software development into practice also for physical modeling. The testing strategy that is used within the Modelica IDE OneModelica from which the requirements for MoUnit arose, is introduced using an example of linear water wave models. The implementation and features of MoUnit are described and its flexibility is exhibited through two test cases. It is outlined, how MoUnit is integrated into OneModelica and how the tests can be automated within continuous build environments.

*Keywords:* MoUnit, OneModelica, Modelica, test framework, automatic testing, verification

## 1 Introduction

An important part of the process of developing physical models is model testing since it greatly increases the probability that the expected behavior is accurately modeled. Within software development it is convenient to create tests and test suites using test frame-

works like JUnit<sup>1</sup>. The use of these test frameworks ultimately lead to a “test first” development approach, i.e., creating tests before actually developing the software parts that must conform to the tests. Also, engineers creating physical models can benefit from a test driven development. Immediate feedback about incorrect model changes can assist in keeping the models consistent during their lifecycle in the modeling process.

By using fine-grained tests for single components, errors in composed models can be traced back to the erroneous element. This also simplifies the development in teams as one modeler's changes may have a negative influence on another modeler's models. However, test-based development as known from software engineering is hard to maintain for physical model developed with Modelica. While the algorithmic parts of models could be checked in a similar way, the behavior expressed by equations cannot be tested directly since the usage of time as a parameter makes it necessary to perform simulations.

A reasonable solution for this is the use of regression tests where reference data is used as a base for comparison with results from subsequent simulations. When models are altered, the result can be compared to the reference files to check if the behaviour is still as expected. The two commonly used Modelica simulation tools OpenModelica<sup>2</sup> and Dymola<sup>3</sup> use regression tests for checking if changes made in the compilers still result in valid simulations as well as to allow users to create regression tests for model development.

Although these kind of tests already aid the development process of physical models, regression tests may not be sufficient to find all problems that may appear during the development and the tools provide a non-uniform way of defining test cases. With our test framework MoUnit we aim at facilitating test case and test suite definition for single model components as

<sup>1</sup><http://www.junit.org>

<sup>2</sup><https://www.openmodelica.org/>

<sup>3</sup><http://www.dymola.com>

well as groups of models. Besides, the tests should be executable with various simulation tools as well as in different environments, e.g., directly inside the Modelica IDE OneModelica<sup>4</sup>, or in continuous build environments like Hudson<sup>5</sup>, which is currently in use for OneModelica and OpenModelica development. Moreover, we want to allow users to extend MoUnit in order to re-use their already implemented test functionality as well as making it possible to create more sophisticated tests than regression tests.

In this paper, we demonstrate how the user can create test cases for automatic testing. The user can use arbitrary simulation tools, compare the results to reference data and to the results of a second experiment. Thereby, it is possible to compare simulation tools to each other or investigate the impact of different solvers on the simulation results without the need to create additional reference files. Moreover, we demonstrate the extensibility of the test framework for example through the implementation of a test component for regression test of equidistant result files. As a second tester component we implemented the calculation of basic statistics. This allows us to validate stochastic properties of our Modelica irregular water wave models by comparing to results from the commercial software ASAS WAVE<sup>6</sup>. Here it is advantageous that several input formats are supported in order to use data from tools that are not Modelica-based. Thus, calculations from analytic formulae producing numerical results can also be used for testing in our framework.

The remainder of this paper is structured as follows: In Section 2 we describe the project structure of Modelica projects in OneModelica. Separation into projects allows to separate code for testing from models containing the physical behavior. The test language is described in Section 3 along with an explanation of how the test framework can be extended. The evaluation in Section 4 demonstrates how the water wave models developed at Fraunhofer Institute for Wind Energy and Energy System Technology (Fraunhofer IWES) are tested using our framework. Finally, Section 5 concludes our work and gives an outlook on how we plan to further enhance the test framework in the future.

## 2 Testing Modelica Models Within OneModelica

Testing is a crucial part of model development. The following aspects of a model should be checked: whether it (a) can be simulated without errors, (b) delivers the expected results, and (c) represents the reality appropriately. Furthermore, when component models are developed and/or modified it also has to be checked whether the composed models deliver the expected results. That is, the robustness of a component model in various situations has to be ensured as — depending on the complexity of the model — even a small change might lead to unexpected results. Testing a model in different situations can be a tedious process as it involves a lot of “playing around with parameters” and waiting for simulations to finish. All these points are reasons for automated testing during model development.

The testing strategy which is presented herein and from which the requirements for the development of MoUnit arose, is closely tied to the Modelica IDE OneModelica. In OneModelica, models are organized in model projects [2]. This approach allows to have two model projects for each component model that has to be implemented. The first one contains all the physical system equations and model logic. However, the models are not yet simulatable because the parameters do not have values yet — as they should be modified by the user when the model is parameterized for various application scenarios. The second one contains the actual test models. The test models contain instances of the models taken from the original model project. The modifications of the original models are done with parameter settings that correspond to defined test case scenarios. This could also be a special set of parameters that has caused problems in the past and it should be ensured for future simulations that it will not occur again. This strategy is somewhat borrowed from the software development: JUnit test plug-ins will be separated from the actual Java plug-ins to divide program logic from the test. The use of instances of the models to be tested rather than extending it, is based on the fact that test models can also be seen as “best practice” examples: a look at the test models shows how the model to be tested should be used. However, if this aspect is not important, it is also possible to use a test model that extends the model to be tested within MoUnit. This would avoid possible inconsistencies between the physics and test model code that is duplicated such as parameter units. Using the ex-

<sup>6</sup><http://www.ansys.com/Products/Other+Products/ANSYS+ASAS>

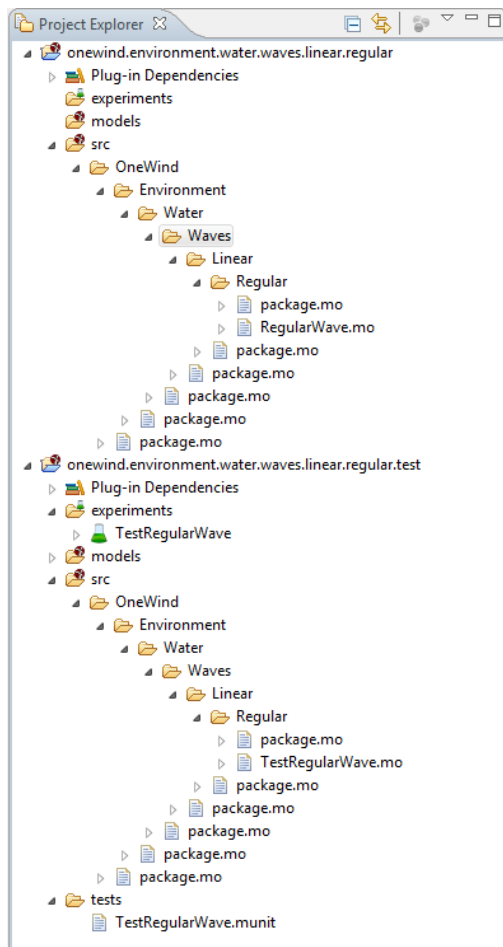

Figure 1: Model projects for both model logic and test models for regular water waves

ample of Modelica models for regular water waves, this is illustrated in Figure 1: The test model project has the same name as the original model project, but with an appended `.test`. This makes it clearly distinct as a test project for all the developers, who work on the models. As can also be seen in Figure 1, the test model project contains experiments that simulate the test models. The structure of the model to be tested and the testing model is shown in Listing 1: the model `RegularWave` has the parameter instances and equations, while the model `TestRegularWave` has an instance of type `RegularWave` and modifies the corresponding parameters. The experiments that are used to simulate the test models are set up manually. They can also be simulated manually during the model development. However, once the number of models and functions has exceeded some threshold been created, manual execution of all the experiments becomes too cumbersome. This is the point where MoUnit should be used. The necessary files for automated execution

```
model RegularWave
  "kinematics of a regular linear wave"
  import SI = Modelica.SIunits;
  import NonSI =
    Modelica.SIunits.Conversions.NonSIunits;

  parameter SI.Height H "wave height";
  parameter SI.Period T "wave period";
  parameter NonSI.Angle_deg epsilon "phase";
  // rest of parameters omitted

equation
  // model logic is placed here
end RegularWave;

model TestRegularWave
  "test model for 'RegularWave'"
  import SI = Modelica.SIunits;
  import NonSI =
    Modelica.SIunits.Conversions.NonSIunits;

  constant SI.Height H = 5;
  constant SI.Period T = 11;
  constant NonSI.Angle_deg epsilon = 12;

  RegularWave regularWave(H = H, T = T,
    epsilon = epsilon
    // rest of modifications omitted
  ) "instance to be tested";

equation
  // test logic like assert statements
  // is placed here
end TestRegularWave;
```

Listing 1: Example for model and corresponding test model

of the experiments are stored in the test model project as shown in Figure 1. These files enable checking that all the models that have been implemented in the original model project are fulfilling the three properties mentioned above: it can be easily seen if a simulation crashes and if the implementation of the model works correctly by comparing it to reference data that can either come from other simulation tools, measurements, or analytical solutions.

### 3 Implementation of the Modelica Test Framework

For the development of valid physical models with Modelica it is vital to define test cases to check that model changes do not negatively affect simulation results. A common way to assure this is using regression tests. This is used by the OpenModelica development group using their framework to test compiler changes by comparing results of simulations to reference data. In the same way Dymola's model management library allows performing regression tests with

Modelica models.

The goal of MoUnit is to provide test-driven physical model development with Modelica. For this purpose we implemented a test framework that is integrated into the Modelica IDE OneModelica and is flexible to be also used in automatic build environments like Hudson. A special test language has been defined that can be parameterized with custom test components and test result listeners which are responsible for processing test results appropriately.

In the following, the test language is described that has been developed with Xtext [3]. It allows defining test cases and test suites for automatic execution. Additionally, the extension mechanism is explained to show how custom test components can be registered allowing users to write test cases for special purposes — for example, basic statistics analysis. Subsequently, the test runner that performs the test execution is described and the registration of listeners is demonstrated. The listener mechanism allows to use MoUnit in different environments, e.g., by displaying the test results visually inside OneModelica or by generating text files for the integration of tests in continuous build environments like Hudson. We have implemented an ANT task that is executed by Hudson. The task adds a listener to the test runner creating a XML file for the documentation of the test results. The result file can then be used by Hudson for error reports.

### 3.1 Test Definition Language

Xtext is a tool for textual language development. By providing a grammar definition of a language, editors and views can automatically be generated with helpful functionality like syntax highlighting and syntax checking. The Modelica editor being the basis for OneModelica has been developed with Xtext. Parsed documents are represented as Ecore-based [4] parse trees and can be used along with other Ecore-based languages (e.g., cross-references between elements of different languages are supported). Since mandatory components for automatic test execution in our IDE are defined as Ecore-models, those components can easily be re-used for MoUnit.

Two components can be defined with the test language that are comparable to concepts used by the test framework JUnit for Java code: Test cases and test suites. Test cases (see Listing 2) define the basic elements that are needed for a test to run while test suites (see Listing 3) combine test cases and other test suites. Hence, a set of test cases can be accumulated to test the correct behavior of interacting Modelica models.

```
name TestCase1
experiment ToTest
file "pathToFile.mat"
compare {
    qualifiedname.*
    test.qn -> reference.qn

    TestComponent {
        attribute = 1.e-5
    }
    error "Error message"
}
```

Listing 2: Example of a Test Case Definition

```
suite AllTests:

    TestSuite1,
    TestCase1
```

Listing 3: Example of a Test Suite Definition

Test cases define names that make them referenceable and thus usable in test suites. The `experiment` keyword states that a Modelica experiment is used in the test. Modelica experiments in OneModelica can use several tools for simulation, including OpenModelica and Dymola. For regression tests a path to a reference file is provided following the keyword `file`. Several checks were implemented to display problems to the user, e.g., when the provided file cannot be found or the experiment is set to leave the Dymola window open after simulation for post processing. This would cause the test execution to pause until the user closes the window manually. It is also possible to directly compare the test results of two experiments by using a second experiment instead of the reference file. This can help to ensure that the results of simulations with OpenModelica are the same as those obtained from simulations with Dymola. Another possibility is to check if the results are equal for different kinds of solvers.

It is also possible to compare two result files with each other, e.g., when it is desired to compare results from other modeling tools and languages. The result files can be in `.mat` format as provided by OpenModelica and Dymola (textual or binary format) as well as in comma separated values format. Moreover, the user can also create results based on some analytical formulae, if it is not desired to implement the analytical result as a test component to register it to the test framework, and save them in one of the supported formats instead.

Simulation result files can be referenced by abso-

lute or relative paths. Using relative paths, files can be put into a project inside OneModelica's workspace and can be synchronized by multiple users with source code management tools like SVN. Since simulation result files might be large, it may be necessary to use network drives for storage. This can be done by using absolute paths that can be prepended with the prefix \$. The prefix will be replaced by a user defined path. This way tests are re-usable for other users, and the prefix only has to be configured once per workspace.

Now that the data for comparison is available, the user needs to provide the qualified names of model elements that shall be compared, following the compare keyword. If no element is defined then all time series from the results are compared to each other. The user can use the asterisk character \* to select groups of elements.

Next, test components are referenced that perform the comparison of results. The components are registered via an Eclipse extension point [5, 6]. The test components must implement a predefined interface and need to be modeled with Ecore. Attributes can be defined which must be parameterized by the user. In the provided example a tolerance for the result comparison is defined which will allow a small difference in the result data of the compared time series.

Possible values for the parameterization are Doubles, Integers and arrays of Doubles and Integers. The attributes are looked up by introspection [9] which is used to validate whether the user provides correct input. When the validation is performed a new instance of the test component is created and the parameters are set. Finally the user defines an error message that will be displayed when a test run fails.

Test suites start with the keyword `suite` followed by a name. They contain a list of test cases and additional test suites. All test cases contained in a test suite will be performed when the suite is executed.

### 3.2 Test Execution and Result Processing

The test definitions are processed by a Modelica test runner. The runner is implemented without dependencies to user interface components to allow usage in build environments that do not have graphical user interface installed (e.g., Linux operating systems on dedicated build servers). The test runner executes the experiments used in the test cases and compares the results to the referenced experiments or files. Listeners can be registered to the test runner to be informed about the executed tests and test results. The duration of each test is measured for performance analysis. The

Figure 2: Structure of the Modelica Test Framework

test components must return a status object that provides information about whether the test succeeded or failed. When a test failed, a message must be provided and an optional index (e.g., the time step) can be used to tell the user about the erroneous location in the result file.

Besides the basic information described above, a test component can return arbitrary objects with additional information about an error. This can, for example, be an SWT<sup>7</sup> composite object for visualization inside OneModelica or a file path to a serialized plot which can be used for a test report. The test runner listener is responsible for checking whether it can handle the object or not.

For the visualization of test results in OneModelica we implemented a view (see Section 4) that is comparable to JUnit's test view. Test suites and test cases are displayed as a tree and the nodes are marked according to successful or erroneous execution. While JUnit test cases are based on assert statements that check whether particular parts of code run correctly, we need to compare result files to check whether the desired behavior is matched. This results in a different kind

<sup>7</sup><http://www.eclipse.org/swt/>

of test status visualization where the qualified names of erroneous models is provided and optional graphs can visualize deviations between expected and present values. A JUnit like behavior could be implemented for algorithmic code, e.g. by interpreting the algorithms [1], allowing to check code very fast. However, this is currently not yet supported by MoUnit.

For the integration with automatic build environments we developed an Eclipse ANT task<sup>8</sup>. The task is performed on an Eclipse workspace that contains the Modelica projects as described in Section 2 with experiments and test definitions. The user provides information about which test cases and test suites shall be executed. For test logging we implemented a test runner listener that creates XML files according to the format used by the JUnit ANT task. Hence, failing Modelica tests can be handled in the same way as JUnit tests, e.g. by sending out notification mails to the responsible model developers. The ANT task enables the use of the same test definitions in continuous build environments as well as for manually triggered testing inside OneModelica.

## 4 Evaluation

In the following, the example of linear water wave models is used for the evaluation of MoUnit. These models were developed at Fraunhofer IWES to display both regular and irregular waves according to Airy wave theory with corresponding stretching methods. The underlying theory for these models can be found in standard offshore engineering text books like [7] or [8].

For evaluation purposes, the variable *eta* corresponding to the wave elevation, i.e. the instantaneous wave height at a given position, is used. For a regular linear wave, *eta* is deterministic as it can be displayed by a cosine function. That is, it can be compared to reference data through a regression test. Accordingly, this is used as a first test case denoted as `TestRegularWave`.

The second test case is called `TestIrregularWave` and tests the variable *eta* for an irregular linear wave. In this case, *eta* is stochastic, i.e., a direct comparison of time series to reference data is meaningless unless they are generated with the exact same input. However, this is not always possible, e.g. when the simulated time series are compared to reference data from a different tool or measurements. Instead, the mean

```
name TestRegularWave

experiment
TestRegularWheelerWave
file
"$ /WAVE_WheelerElevation.csv"
compare {

    regularWaveKinematics[1].eta
    -> asas.elevation.eta

    EquidistantTSValidator {
        tolerance=10e-11
    }
    error "Wave elevation does not match."
}
```

Listing 4: Test Definition for Regular Waves

value and the standard deviation of the time series are compared to those of reference data.

For the test case `TestRegularWave` (see Listing 4), we implemented the test component `EquidistantTSValidator`. It can be parameterized with a *tolerance* that represents the acceptable absolute difference between the two compared time series. The input files for the component must have the same length as well as equidistant values. If the input does not match the reference data, i.e., if the absolute difference between input and reference data exceeds the value of *tolerance*, an error will be displayed. The resulting view for our example is shown in Figure 3: the simulation time plus the time used for validating the values is displayed as a sum in the test case tree view. When the user selects the erroneous test, basic information about the location of the first assert failure is provided together with a plot of the two compared curves.

For the test case `TestIrregularWave` (see Listing 5) a test component named `BasicStatistics` has been implemented to compare mean value and standard deviation as described above. The user can provide the parameters *startindex* and *endindex* to define the range of values that shall be checked for the provided input values.

```
name TestIrregularWave

file
"$ /ir_periodical_elevation_dymola.csv"
file
"$ /ir_elevation_asas.csv"
compare {

    modelica.elevation.eta
    -> asas.elevation.eta
```

<sup>8</sup><http://ant.apache.org/>

```

BasicStatistics {
    startindex=0,
    endindex=800,
    meandeviation=0.01,
    stddeviation=0.001
}
error "Basic statistics of wave
    elevation do not match."
}

```

Listing 5: Test Definition for Irregular Waves

Additionally, the user can define the allowed variance of the calculated mean values and standard deviations. Figure 4 shows the resulting view displaying information about the assertions that were violated. While the mean value of the wave elevation matches the reference data, the standard deviation is not acceptable. As for the test case `TestRegularWave`, a plot is provided to visualize the compared values to the user.

## 5 Conclusion and Outlook

In this paper, we demonstrated that the test framework MoUnit developed at Fraunhofer IWES can effectively be used for testing Modelica models by unit testing. We showed that the framework is flexible as it supports multiple simulation tools as well as input files from other tools for result comparison. This allows to check the different behavior of models when using different simulation tools as well as different solvers.

We also illustrated that it is possible to extend MoUnit with custom test components that provide functionality different from regression testing. Using the example of simulating water waves, we compared simulation results of our Modelica models to simulation results of the reference tool ASAS WAVE. The extensibility also allows to add test components that use results from analytical calculations for result validation.

For error reporting, a flexible interface has been defined. We implemented a plot for wave model tests displaying the time series of the data that is being compared together with the corresponding mean values and standard deviations. Thereby, the user can directly investigate the cause for a problem visually. Furthermore, an ANT task has been implemented that executes test suites and registers a listener that serializes a test report in an XML file compatible to JUnit. Hence, the tests can be integrated into a build system for continuous testing.

In the future, we plan to create additional test functionality that allows to test single values of result files. The implementation of test components for analytical

solutions are planned for the models of wind turbine components — as far as they are available. For fast testing of algorithms, it is furthermore desirable and planned to interpret the algorithmic code, e.g. of Modelica functions to allow direct calls and comparison to expected result values.

# Modeling Parameter Sensitivities via Equation-based Algorithmic Differentiation Techniques: The ADMSL.Electrical.Analog Library

Atiyah Elsheikh  
Austrian Institute of Technology, Vienna, Austria  
Atiyah.Elsheikh@ait.ac.at

## Abstract

Parameter sensitivities of mathematical models play a vital rule in many applications of sensitivity analysis. The availability of algorithmic capabilities for representing and computing these quantities is surly advantageous. In this work it is shown how to systematically transform a Modelica library to another library that describes the desired models together with derivatives of model variables w.r.t. model parameters. The produced library remains with the same structure and the underlying models keep the same interface and outlook. The proposed approach relies on novel equation-based algorithmic differentiation techniques that are especially designed for Modelica. The illustration is rather done via a compact library, the open-source ADMSL library, but rich enough to facilitate a lot of representative Modelica language constructs. The ADMSL library is the algorithmically differentiated version of the standard Modelica library subpackage `Modelica.Electrical.Analog.Basic`.

*Keywords:* *algorithmic differentiation; parameter sensitivities; sensitivity analysis, ADMSL, AD of Modelica libraries*

## 1 Motivation to algorithmic differentiation

If you want to draw Bamboos, you should try drawing Bamboos for your whole life, then you might be able to draw Bamboos, an ancient Chinese wisdom. In other words, the earliest modelers have already recognized that there is no model that identically describes the reality up to the tiniest details. This seems to be also the case now days, at least in the field of Systems Biology [27]. However even an elementary model describing a complex system is an essential initial step towards gaining insights and

winning additional knowledge of the modeled system. Via e.g. the availability of further experimental data, the model can be better tuned [5]. Nevertheless, instead of trying to approach a true model for one's whole life, many tools of sensitivity analysis, such as model identification, validation and optimization [11, 12] can help the modelers to realize their visions, hopefully in a reasonable amount of time.

Significant quantities, that can assist the implementation of such computational tools, are parameter sensitivities, i.e. the derivatives of model outputs w.r.t. model parameters. Straightforward ways for evaluating these quantities via finite difference methods are not recommended for accuracy reasons [16]. A more reliable but technically difficult approach is to symbolically derive these quantities and then to evaluate them via a numerical integrator, e.g. the IDAS solver within the Sundials Suite [21].

These factors among other typical applications of mathematical derivatives increasingly attract attention at a special domain of scientific computing called Algorithmic Differentiation (AD) of computer programs [19]. Based on the chain rule of Calculus, procedural compiler methods and other established techniques, many automatic differentiation tools (cf. [www.autodiff.org](http://www.autodiff.org)) are capable of:

- analyzing a large set of computer programs written in many procedural programming languages
- adequately computing new programs additionally representing partial derivatives

The resulting generated programs are typically used for evaluating the derivatives of program outputs w.r.t. program inputs among other directional derivatives.

## 2 Introduction

### AD and the Modelica community

While classical AD techniques and tools are targeting a large scope of developers of mathematical programs, only a tiny part of the Modelica community is explicitly utilizing AD methods, namely tool vendors and developers of Modelica simulation environments. For instance, in [25, 4, 7] the Jacobian is symbolically computed for the task of index reduction and adaptive numerical integration. For the more difficult task of computing parameter sensitivities, some simulation environments such as JModelica [3] and SystemModeler [2] can be used. A translated Modelica model is linked with advanced specialized integrators suite like SUNDIALS capable of evaluating parameter sensitivities [21]. In this context, AD techniques are usually applied at low level C code describing the translated equations.

In contrary, the approach of applying AD techniques directly to the high-level descriptive model represents another attractive option. An example is given by the tool ADModelica [15, 14], which is capable of transforming a given high-level Modelica model into another Modelica model additionally describing parameter sensitivities. Similar works have been also reported with other modeling languages [6, 20]. Nevertheless and even with the availability of open-source developer-oriented compiler tools like OpenModelica [26], the development and maintenance efforts for such a tool attempting to cope with a rich language like Modelica becomes a continuously exhaustive task.

### Contribution

For the first time an equation-based modeling-oriented AD approach for differentiating Modelica libraries is demonstrated. The approach provides the basic guidelines for systematically transforming a library into a topologically-identical algorithmically differentiated library in which parameter sensitivities are additionally represented. By reimporting the augmented library into already existing base models and slightly altering the declaration for specifying the required model parameters w.r.t. which derivatives are sought, parameter sensitivities is represented at the model level. In this sense, transformed library components are overloaded with semantics for describing parameter sensitivities. Using an arbitrary Modelica

simulation environments, parameter sensitivities are directly simulated within the model.

Due to the speciality of the Modelica language and its significant difference from assignment-based procedural languages for which classical AD techniques were designed, new specialized equation-based AD techniques are demonstrated in this work. These techniques, relying on equation-based compiler notions, utilize Modelica powerful capabilities to provide efficient representation of partial derivatives. Consequently, the inclusion of parameter sensitivities within Modelica libraries can be considered from the early design phase or alternatively, existing libraries can be augmented with additional components for describing the required derivatives. In this sense, AD techniques needs to be applied only once and the resulting library can be used for ever.

According to Naumann [24], to master AD concepts, AD users should be first able to manually differentiate their own compact programs before applying AD tools. In this work, the presented techniques are intuitive enough to be systematically applied on manual basis even on sophisticated libraries with complex mathematical models, e.g. ADGenKinetics [10]. In this way, a larger part of the Modelica community can possess the art of self-handling AD techniques along their modeling activities. The presented approach describes the basic steps subject to automation and consideration within realistic Modelica-based AD tools. A comprehensive algorithmic specification of the demonstrated techniques is given in [13].

## 3 General scheme

The key idea of the presented approach is illustrated via the diagram presented in Figure 1. Without loss of generality, a model  $M$  with two connected components  $C_1$  and  $C_2$  is given. The components are mathematically described by Differential Algebraic Equations (DAEs) via the functions  $f_1$  and  $f_2$ , respectively.  $x_i$  and  $p_i$  for  $i \in \{1, 2\}$  correspond to systems variables and model parameters, respectively. The function  $g$  describes a causal or an acausal connection relation between  $C_1$  and  $C_2$ .

The algorithmically differentiated components  $C'_1$  and  $C'_2$  extend the components  $C_1$  and  $C_2$  with the underlying Sensitivity Equation Systems (SESs). A SES is obtained by *forward differentiation* of

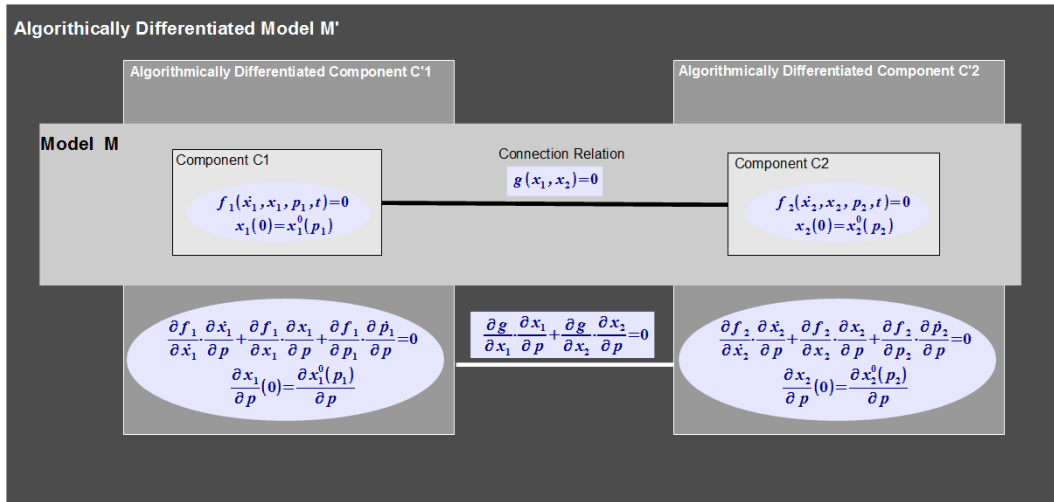

Figure 1: A general block diagram of a model with two connected components and their algorithmically differentiated copies

the original DAE system w.r.t. the model parameters  $p = (p_1 \ p_2)^T$ . The component  $C'_1$  additionally declares the *input Jacobian* of the parameters  $\partial p_1 / \partial p$ , i.e. the derivatives of the local *active parameters* within  $C_1$  w.r.t. the parameters of the whole model  $p$ . In general, the model parameters are of course not known within the separate component  $C'_1$ . Therefore, input Jacobian  $J_p$  is declared w.r.t. arbitrary model parameters  $p$  that are first defined at the model level. An example is given in the next Section. Analogously  $C'_2$  specifies the active local parameters within  $C_2$  via their input Jacobian w.r.t. arbitrary unknown parameters.

An algorithmically differentiated model  $M'$  is obtained by connecting the components  $C'_1$  and  $C'_2$ . The connection relation is similarly described by forward differentiation of the equation system  $g$  w.r.t.  $p$ . The key idea is based on the chain rule of Calculus by which partial derivatives are propagated among components and hence parameter sensitivities of the whole model are inherently present.

There are many structural similarities between the model  $M$  and its AD version  $M'$  [17]:

1. Both models have the same interface in a GUI-editor, the SES remains hidden from the user perspective
2. The Jacobian of the differentiated equation system w.r.t. one single parameter has an identical structure and sparsity pattern of the Jacobian of the original system [23]

3. It can be proven that the structural indices of both models are equal

These characteristics can be utilized for simplifying the compilation phases within a Modelica compiler targeting AD of Modelica libraries and models. The next section provides a simple example illustrating the whole paradigm in Figure 1.

## 4 Illustrative example: The declaration part

### 4.1 The ADMSL library

Based on the techniques presented, an example illustrated on a subpackage of the Modelica standard library (MSL) `Modelica.Electrical.Analog.Basic`. The whole illustration is provided via the open-source ADMSL library [1]. The ADMSL library serves as an experimentation platform for:

1. Illustrating the basic steps for performing AD of Modelica libraries
2. Identifying the best capabilities of the Modelica language relevant for expressing parameter sensitivities at the library components level
3. Recognizing current limitations from expressibility perspective with which automatic code generation becomes less systematic

## 4.2 Code generation rules

In Naumann [24], basic code generation rules for performing AD of procedural languages have been presented. Analogously, in this paper simple code generation rules, however, for the Modelica language are demonstrated. These Modelica-specialized rules serve as main guidelines for performing AD of Modelica libraries. Note that the presented rules are distinguishably different than those provided for classical languages. For a complete understanding of the following subsections, the reader is recommended to consult the subpackage `Modelica.Electrical.Analog`.

### Declaration rule 1: structure duplication

When performing AD of a Modelica library, all packages and subpackages are simply duplicated. For instance, the subpackage `ADMSL.Electrical.Analog` corresponds to the subpackage `Modelica.Electrical.Analog`. Within each package, model components with the same names are placed. Each model component extends the original components. For instance, the corresponding AD version of the connector `Pin` becomes:

Listing 1: AD version of `Pin`

```
connector Pin
  extends Modelica.Electrical.Analog.
    Interfaces.Pin;
  ...
end Pin;
```

For components declaring these Pins, the corresponding AD version, e.g. of the `OnePort` component, should declare the corresponding AD versions of Pins. This is done by redeclaring replaceable Pins:

Listing 2: AD version of `OnePort`

```
partial model OnePort
  extends
    Modelica.Electrical.Analog.
    Interfaces.OnePort (
      redeclare ADMSL.Electrical.Analog.
        Interfaces.PositivePin p,
      redeclare ADMSL.Electrical.Analog.
        Interfaces.NegativePin n);
  ...
end OnePort;
```

The above code assumes that the electrical pins `p` and `n` are declared as replaceable. However, this is not the case in the latest Modelica library version 3.2. Alternatively, as a temporary solution, the original `TwoPort` model has been slightly modified and placed under `Analog.Interfaces.Bases` package as shown in Appendix A. Similarly, for models (e.g.

`Capacitor`) extending partial models (e.g. `OnePort`), their AD versions need to extend the AD versions of these partial models, for example:

Listing 3: AD version of `Capacitor`

```
model Capacitor
  extends Bases.Capacitor (
    redeclare replaceable class
      OnePort = ADMSL.Electrical.Analog.
        Interfaces.OnePort);
  ...
end Capacitor;
```

### Declaration rule 2: duplication of data segments

Any new component needs to reference the global number of active parameters w.r.t. which derivatives are sought. This is done by extending the component `ADMSL.Interfaces.GradientInfo` declaring global gradient related information:

Listing 4: Declaring the number of gradients

```
outer parameter Integer NG
  "dimension of gradient";
```

The parameter is declared as outer utilizing implicit connection mechanisms. It gets first initialized only by explicit declaration defining the same parameter as inner at the top level model. Accordingly, for all model components a *derivative object* (i.e. the gradient) is additionally declared for each real variable or parameter within the corresponding component, e.g. the AD version of the connector `Pin`:

Listing 5: AD version of `Pin`

```
connector Pin
  extends ... // as before
  extends ADMSL.Interfaces.GradientInfo;
  Real g_v[NG]
    "gradient of the voltage";
  flow Real g_i[NG]
    "gradient of the current";
end Pin;
```

The idea is simple, potential derivative objects are associated with variables while flow derivative objects are associated with flow variables. Similarly, in the model capacitor:

Listing 6: Declaration part of `Capacitor`

```
model Capacitor
  extends ...; // as before
  parameter Real g_C[NG] = zeros(NG);
  ...
end Capacitor;
```

Here, a derivative object initialized to the zero vector is associated with the parameter `C`. Each entry of

a gradient represents the derivative w.r.t. a parameter specified via the input Jacobian at the top model. So far the main rules for altering the declaration part has been demonstrated. In the next section, further rules for deriving the sensitivity equations are illustrated.

## 5 Illustrative example: The equation part

### 5.1 Modeling SES in gradient format

Assume that a given Modelica component  $C$  is described more or less DAE system (without discrete variables):

$$F(\dot{x}, x, p, t) = 0 \quad , \quad x(t_0) = x_0(p) \quad (1)$$

where  $x(t) \in R^n$  and  $p \in R^m$  represent state variables and parameters, respectively. Additionally, assume that  $F : R^{2n+m+1} \rightarrow R^n$  is continuously differentiable w.r.t.  $\dot{x}, x$  and  $p$ . Required is an additional component  $C'$  that augments  $C$  with additional equations for describing the time-dependent parameter sensitivities  $(\partial x / \partial p)(t) \in R^{n \times m}$ . As mentioned before,  $C'$  needs to include the *sensitivity equation subsystems* (SESub):

$$F_x \dot{s}_i + F_x s_i + F_{p_i} = 0 \quad , \quad s_i(t_0) = \frac{\partial x_0(p)}{\partial p_i} \quad (2)$$

where  $s_i = \frac{\partial x}{\partial p_i}$  for  $i = 1, 2, \dots, m$

SESub is obtained by differentiating all equations w.r.t. desired parameters. This is a large equation system of dimension  $m \cdot n$ . Explicit listing all these equations makes  $C'$  not compactly implemented.

To overcome this drawback, Modelica array capabilities can be utilized if the equation system 2 is implemented in gradient format. Within a model component corresponding to a DAE of the form (1), assuming that  $F_i$  corresponds to the  $i$ -th equation in  $F$  let  $F_x$  be defined as follows:

$$F_x = \left[ \frac{\partial F_i}{\partial x_j} : i, j = 1, 2, \dots, n \right] \in R^{n \times n}$$

and let  $F_{\dot{x}}, F_p, \dot{x}_p$  and  $x_p$  be analogously defined. Furthermore, let the input Jacobian  $J_p$  be defined as follows:

$$J_p = \left[ \frac{\partial p_i}{\partial p_j} : i, j = 1, 2, \dots, m \right] \in R^{m \times m}$$

A typical case is to set  $J_p = I_m$ , the identity matrix, for a set of independent parameters. Then the corresponding differentiated equation w.r.t. a parameter  $p_j$  is derived from Equation (2) as follows:

$$\sum_{l=1}^m \left[ \sum_{k=1}^n [F_{\dot{x}}(i, k) \dot{x}_p(k, l)] + \sum_{k=1}^n [F_x(i, k) x_p(k, l)] + \sum_{k=1}^m [F_p(i, k) J_p(k, l)] \right] J_p(l, j) = 0 \quad (3)$$

Using Modelica array capabilities and assuming that the given set of parameters is independent (i.e.  $\partial p_i / \partial p_j = 0$  for  $i \neq j$ ), Equation (3) can be rewritten in a gradient format comprising  $m$  equations:

$$\sum_{k=1}^n [F_{\dot{x}}(i, k) \dot{x}_p(k, :)] + \sum_{k=1}^n [F_x(i, k) x_p(k, :)] + F_p(i, :) = 0 \quad (4)$$

for  $i = 1, 2, \dots, n$  where  $A(i, :)$  represents the  $i$ -th row of a matrix  $A$ .

### 5.2 Code generation rules

#### Forward differentiation rule 3: deriving sensitivity equations

Using Equation (4), SES of simple model components can be easily implemented. For instance the equation part of the component `ADMSL.Analog.Basic.Capacitor` becomes:

Listing 7: Equation part of Capacitor

```
model Capacitor
  extends ...;
  ...
  equation
    g_i[1:NG] = g_C[1:NG] * der(v) +
                C * der(g_v[1:NG]);
  end Capacitor;
```

Deriving SES for simple mathematical formulas like the previous one is straightforward. For long complex formulas, common computer algebra packages can be used. However, it is recommendable to employ the equation-based AD techniques illustrated in Section 6.

#### Forward differentiation rule 4: handling blocks within flow control

Modelica, as many other languages, provides classical language constructs for flow control such as `for`, `while`, `if`,...etc. In classical AD concepts, assignment blocks within typical control flow constructs

(e.g. for, if, ...etc.) are directly differentiated as an independent block. Although such constructs are interpreted differently in an equation-based context, the generation of SES within such blocks are similarly intuitive. For example, the equation part of the model Analog.Examples.Utilities.NonlinearResistor is implemented as follows:

Listing 8: Equation part of NonlinearResistor

```
model NonlinearResistor
...
equation
  i =
    if (v < -Ve) then
      Gb*(v + Ve) - Ga*Ve
    else if (v > Ve) then
      Gb*(v - Ve) + Ga*Ve
    else
      Ga*v;
end NonlinearResistor;
```

The implementation of its AD version becomes:

Listing 9: Equation part of NonlinearResistor

```
model NonlinearResistor
...
equation
  g_i[:] = if (v < -Ve) then
    g_Gb[:] * (v + Ve) +
    Gb * (g_v[:] + g_Ve[:]);
  - (g_Ga[:] * Ve + Ga * g_Ve[:]);
  else if (v > Ve) then
    ...
  else
    ...;
end NonlinearResistor;
```

## 6 Equation-based AD

So far, the demonstrated components have short equations that can be easily differentiated. In this section, an equation-based AD technique, especially designed for the Modelica language, is shown. In the first ever algorithmically differentiated library, ADGenKinetics, the following equation corresponding to the convenience kinetics of chemical reaction rates

$$v = \prod_a \frac{K_{A_a} + [A_a]}{K_{A_a}} \cdot \prod_b \frac{K_{I_b}}{K_{I_b} + [I_b]} \cdot \frac{V_{max}^{fwd} \prod_i \frac{[S_i]}{K_{mS_i}} - V_{max}^{bwd} \prod_j \frac{[P_j]}{K_{mP_j}}}{\prod_i \left(1 + \frac{[S_i]}{K_{mS_i}}\right) + \prod_j \left(1 + \frac{[P_j]}{K_{mP_j}}\right) - 1} \quad (5)$$

has been easily differentiated using the demonstrated technique, consult [10] for more details about this

equation and the ADGenKinetics library. In this paper, the technique is illustrated on a more simple equation within the model Analog.Basic.Conductor which implements conductance as:

$$G_{actual} = \frac{G}{(1 + \alpha (T_{hp} - T_{ref}))} \quad (6)$$

While this formula can be used within a Calculus exam, the technique is applicable on formulas like (5).

### 6.1 Classical AD techniques

The fundamental terminologies and concepts of classical AD techniques for assignment-based procedural languages have been largely developed decades ago. Application of classical AD techniques is not best suitable to be applied on equation-based languages due to [15, 13]:

- Classical AD techniques are mainly designed for explicit assignments and not implicit equations
- Excessive number of expressions evaluations is performed
- Excessive storage for temporary variables and their gradient computations is needed

In order to overcome these drawbacks, an equation-based technique relying on fundamental notions of equation-based languages has been designed.

### 6.2 Equation-based AD technique

Figure 2: The AST of Equation 6 and the enumeration of expression subtrees

### Preprocessing: Intermediate elementary equations

The key idea of enabling differentiation of a complex equation is to decompose it into *elementary equations*. Each equation is composed of a unitary operator (e.g.  $+$ ,  $-$ ), a binary operator (e.g.  $+$ ,  $-$ ,  $*$ ,  $\square$ ) or an intrinsic function (e.g.  $\sin$ ,  $\cos$ ). By constructing the abstract syntax tree (AST) of the equation, elementary equations can be computed. In Figure 2, non-leaf nodes correspond to operands. Leaf nodes correspond to identities. Identities are distinguished according to their variability, e.g. constants, parameters and variables. Each subtree  $T_k$  is intuitively indexed with a binary number  $k$  according to its position in the tree. Each node with index  $k$  has children of index  $2k$  and  $2k + 1$ , if any. Intermediate equations and their derivatives can be easily computed via a left-right-node (LRN) traversal as follows:

$$\begin{aligned}
 T_{1111} &= T_{hp} - T_{ref} \\
 \Rightarrow T'_{1111} &= T'_{hp} - T'_{ref} \\
 T_{111} &= \alpha T_{1111} \\
 \Rightarrow T'_{111} &= \alpha' T_{1111} + \alpha T'_{1111} \\
 1/T_{11} &= 1 + T_{11} \\
 \Rightarrow T'_{11} &= -T'_{111} T_{11} T_{11} \\
 T_1 &= G T_{11} \\
 \Rightarrow T'_1 &= G' T_{11} + G T'_{11} \\
 \Rightarrow G'_a &= T'_1
 \end{aligned}$$

where

$$T'_k = \left( \frac{\partial T_k}{\partial p_1}, \frac{\partial T_k}{\partial p_2}, \dots, \frac{\partial T_k}{\partial p_m} \right)$$

Here, only intermediate equations corresponding to non-leaf nodes are considered. Moreover, Modelica capabilities are utilized for providing specialized treatment of the division operator, the most expensive arithmetic operator. This is done in a way that the let derivatives don't include further divisions.

### Processing: Accumulation

The previous intermediate equations though represent desired partial derivatives, however it requires a lot of storage for  $T'_k$ . To overcome this drawback one can rather iteratively accumulate the partial derivatives, within the same LRN traversal of the AST. On a manual basis, this corresponds to an iterative process of copy and paste of the intermediate equations one after another. In this way, the *accumulated intermediate*

*equations* become:

$$\begin{aligned}
 T'_{1111} &= T'_{hp} - T'_{ref} \\
 T'_{111} &= \alpha' T_{1111} + \alpha (T'_{hp} - T'_{ref}) \\
 T'_{11} &= -(\alpha' T_{1111} + \alpha (T'_{hp} - T'_{ref})) T_{11} T_{11} \\
 T'_1 &= G' T_{11} \\
 &+ G (-(\alpha' T_{1111} + \alpha (T'_{hp} - T'_{ref})) T_{11} T_{11}) \\
 \Rightarrow G'_a &\equiv T'_1
 \end{aligned}$$

Now, it is enough to declare only one derivative object for  $G_a$ .

### Postprocessing: Common subexpressions

The accumulated intermediate equations contain multiplicative term that are going to be evaluated  $m$  times. Within the same LRN-traversal, these multiplicative terms (e.g.  $\alpha T_{11} T_{11}$ ) can be rather stored in an a local variable. These terms are stored in local variables `adl_*` within the Conductor model:

Listing 10: The AD version of the Conductor model

```

model Conductor
  extends ...;
  ...
protected
  Real T_1111;
  Real T_111;
  Real D_11;
  Real adl_11_1;
  Real adl_11_2;
  Real adl_11_3;
  Real adl_1_1;
  Real adl_1_2;
equation
  T_1111 = T_heatPort - T_ref;
  T_111 = alpha * T_1111;
  1/D_11 = 1 + T_111;
  adl_11_1 = - D_11 * D_11;
  adl_11_2 = adl_11_1 * alpha;
  adl_11_3 = T_111 * adl_11_1;
  adl_1_1 = G * adl_11_3;
  adl_1_2 = G * adl_11_2;
  g_G_actual[:] = g_G[:] * D_11 +
    adl_1_1 * g_alpha[:] + adl_1_2
    * (g_T_heatPort[:] - g_T_ref[:]);
  g_i[:] = g_G_actual[:] * v
    + G_actual * g_v[:];
  g_LossPower[:] = g_v[:] * i
    + v * g_i[:];
end Conductor;

```

This is an optional step, particularly, if the used Modelica compiler is capable of recognizing common subexpressions and treating them adequately. However this step still can be used for coming up with an

efficient compact representation of the partial derivatives.

## 7 Illustrative Example: The top model

Having performed equation-based AD of the Electrical.Analog sub-package, then parameter sensitivities of the electrical circuit in Analog.Basic.Example.ChuaCircuit are implicitly represented by simple slight modification:

- reimporting the AD version of the library and
- specifying the input Jacobian

Listing 11: The AD version of the ChuaCircuit model

```
model ChuaCircuit
  "Chua's circuit, ns, V, A"
  // import Modelica.Electrical.
    Analog.Basic;
  import ADMSL.Electrical.Analog.Basic;
  // import Modelica.Electrical.Analog.
  //   Examples.Utilities;
  import ADMSL.Electrical.Analog.
    Examples.Utilities;
  import Modelica.Icons;
  extends Icons.Example;
  import ADMSL.Utilities.*;
  inner parameter Integer NG = 8;
  Basic.Inductor L(L=18,
    g_L=unitVector(1,NG));
  Basic.Resistor Ro(R=12.5e-3,
    g_R=unitVector(2,NG));
  Basic.Conductor G(G=0.565,
    g_G=unitVector(3,NG));
  Basic.Capacitor C1(C=10, v(start=4),
    g_C=unitVector(4,NG));
  Basic.Capacitor C2(C=100,
    g_C=unitVector(5,NG));
  Utilities.NonlinearResistor Nr(
    Ga(min=-1) = -0.757576,
    g_Ga = unitVector(6,NG),
    Gb(min=-1) = -0.409091,
    g_Gb = unitVector(7,NG),
    Ve=1,
    g_Ve = unitVector(8,NG));
  Basic.Ground Gnd
equation
  // same as before
  ...
end ChuaCircuit;
```

Figures 3 and 4 show some results of the parameter sensitivities.

Figure 3: The sensitivities of the current at all components (i.e. L.i, Ro.i, G.i, C1.i, C2.i, Nr.i, Gr.i) w.r.t. the inductance L.L

Figure 4: The sensitivities of L.v w.r.t. all parameters (i.e. L.L, Ro.R, G.G, C1.C, ... etc.)

## 8 Summary and outlook

In this paper, an equation-based methodology for AD of Modelica libraries has been comprehensively demonstrated. The new equation-based AD techniques have been designed for the Modelica language. With few simple code generation rules, parameter sensitivities of base models are additionally described. These rules make use of the art of AD to let modelers themselves be capable of manually differentiating large-set of models. Once a library is already differentiated for once, it can be used forever. The whole work serves as an experimentation platform for the implementation of AD tool. Already a lot of the functionalities are implemented within the tool ADModelica [14].

Further ongoing works are running on several dimensions:

- Ensuring that all used terminology is conform to the Modelica specification
- choosing the most proper constructs allowing further extension of this library to be compilable with arbitrary simulation environments

- Implementing unit tests not only for single components but also to ensure the correctness of intermediate components, processed and postprocessed classes
- Implementing further useful sensitivity-related functionalities, e.g. scaled sensitivities, finite difference functions, etc.
- Utilizing Modelica capabilities for operator overloading

Finally, there are further two issues that are worth to mention. First, although normal numerical solvers not especially designed for sensitivity analysis are used, the expensive computation of parameter sensitivities can be reduced by following a numerical integration approach based on Dicknson [8]. Smaller subsets of parameter sensitivities are considered one after another rather than considering the whole SES [9]. The structure of the proposed gradient-oriented code easily suggests that. Moreover, this approach is parallelizable in a scalable manner [22].

Second, the presented approach in this work is restricted to continuous-time based components by which large set of already existing libraries can be considered. However, theorems and concepts for handling discontinuous functions and hybrid systems already exist [18], out of which further extensions to this work can be considered.

## A Some modified components in the Modelica.Electrical.Analog library

```
ADMSL.Electrical.Analog.Interfaces.  
Bases.OnePort
```

The TwoPin model with the MSL is slightly modified by letting the declared connectors become replaceable as follows:

## Abstract

This paper describes the new OpenModelica Compiler-Compiler (OMCC) including a parser generator, OMCCp which is based on an LALR parser generator extended with advanced error handling facilities. It is implemented in the MetaModelica language with parsing tables generated by the tools Flex and Bison. It is integrated with the MetaModelica semantics specification language, based on operational semantics for generating executable compiler and interpreter modules.

The OMCCp parser generating part of OMCC is being used for the full Modelica language grammar as well as for the language extensions of MetaModelica, ParModelica, and Optimization specifications. The generated parsers have reasonable performance compared to other parser generators.

*Keywords:* Modelica, MetaModelica, Flex, Bison, ParModelica, Optimization, OMCCp

## 1 Introduction

The OpenModelica environment currently makes use of the tool ANTLR (Another tool for Language Recognition) [11] to generate the parser for the OpenModelica Compiler (OMC). In this paper we present an alternative to ANTLR, the new OpenModelica Compiler-Compiler parser generator (OMCCp), developed within the OpenModelica project. The tool is implemented in MetaModelica which is an extension of the Modelica language for modeling the semantics of languages. The work [9] [11] is integrated with the recently developed bootstrapped OpenModelica compiler (OMC) [14].

The ANTLR parser generator which has been used in the OpenModelica project for several years has well

known disadvantages including memory overhead, bad error handling, and lack of type checking. Also it does not generate directly MetaModelica code for building the Abstract Syntax Tree (AST).

Since the AST nodes are initially generated by C functions (for later conversion into MetaModelica garbage collected memory space) without strong type checking in the C language, small errors in the semantic actions of the grammar are not detected at generation time and can give rise to hard-to-find errors in the generated code (even small errors in the grammar actions C code lead to segmentation faults).

When the semantic actions can be specified in MetaModelica and the AST builder directly generates the MetaModelica code, the above mentioned errors can be completely eliminated.

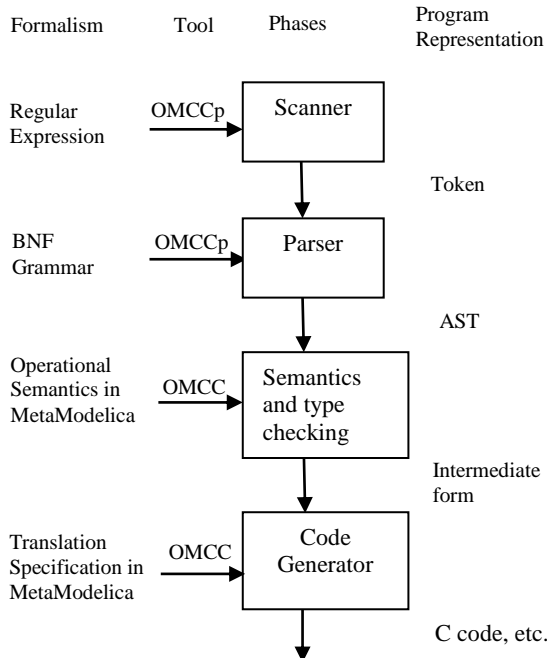

The need for good error handling as well as avoidance of certain AST-building errors has motivated the development of the Modelica based parser generator with good error handling [9][11].

This paper is structured as follows: Section 2 describes the different steps involved in designing a compiler from different specification formalism. Section 3 presents the error-handler features added to the tool and also illustrates the different types of error handler messages displayed to the user in the case of erroneous programs. Section 4 explains the main MetaModelica language constructs used in this implementation for generating the Abstract Syntax Tree (AST). Section 5 explains the OMCCp tool design and architecture and Section 6 presents test results and performance measurements. Finally Section 7 concludes the paper summarizing achieved results.

## 2 Background

### 2.1 Generating Compiler Phases

A compiler can be generated from a formal specification in different formalisms, as depicted in Figure 1.

**Figure 1.** Design stages of a compiler from different specification formalism

Figure 1 describes the stages involved in generating a compiler from specifications in different formalisms. Generally a compiler is divided into two parts: the front-end and the back-end. The Scanner and Parser constitute the front-end phase whereas Optimization and Code generator constitute the back-end phase of the compiler. In this paper we focus on the front-end parts of the compiler.

### 2.2 Lexical Analysis

The Lexical analysis, performed by a scanner, is the first stage of the compilation process. It receives the source code as input and generates tokens. It identifies the special tokens defined by a language making it simpler for the next phase of the compiler. The tokens are usually specified by using Regular Expressions.

There are several tools available that automate the process of constructing the transition rules to identify the tokens for a scanner. We use the Flex tool [13] for this purpose which generates C code; the generated C code is later used by OMCCp to generate the appropriate lexer components in MetaModelica [1] [9] [11].

### 2.3 Syntax Analysis

The syntax analysis (also called parsing) is the second stage of the compilation process. The parser takes the tokens generated by the lexer and determines whether the tokens are constructed according to the rules of the grammar. During this process the Abstract Syntax Tree (AST) is created if the input conforms to the defined grammar. Otherwise an error message is reported.

The AST is used as input to the back-end. The back-end uses the AST for type checking, optimization and finally generates machine specific code. The grammar rules are usually specified in the form of BNF (Backus-Naur Form). We use the popular Bison tool for writing the grammar rules; the generated tables are used by OMCCp as part of the parser algorithm written in MetaModelica that interprets these parse tables [1][9][11].

## 3 Error Handling

The error handling techniques in the front-end are more relevant during the Syntax analysis phase than in the lexical analysis phase. Only a few errors can be detected by the lexical analysis, such as non-terminated comments, use of invalid characters, or unrecognized tokens. One possible error-recovery strategy implemented in a lexer is to ignore invalid characters from the input and continue the process.

The error handling techniques can be divided into two categories: Error recovery techniques and error message display. Error recovery techniques are concerned with how the parser can keep parsing after an erroneous token is found. Error message display concentrates on how to present useful hints for the developer in order to correct the source code. In this section we will present the two topics for error handling during the syntax analysis phase [1] [9] [11] [2] [4].

### 3.1 Error Recovery

Error recovery techniques try to improve the quality of the parser by different techniques such as primary recovery or secondary recovery. The first condition to start the recovery is to access the configuration obtained when the token preceding the error token was shifted onto the stack

Primary recovery techniques are related to single token modification from the list of tokens. Single modification is only possible when the error is classified as simple. Such a modification can be insertion, deletion, substitution, or merging.

Each attempt to perform a repair is known as a trial. A common technique for searching the trials is to attempt to repair the error token by performing one of these operations: *merging*, *insertion*, *substitution*, *scope recovery* and finally *deletion*. In the case of insertion or substitution a set of possible candidates should be generated and then from there a single candidate or none should be selected.

When the error requires more than a simple modification, the list of tokens needs to be reduced. This can be done by discarding tokens that precedes or follows the error token. This is known as secondary recovery [1] [9] [11] [2].

## 3.2 Error Messages

OMCCp uses a primary recovery technique to display all the possible recovery candidates to the developer. When an error is found, the parser fires the error handler function including the environmental variables that contain the actual configuration of the parser and the backed up configuration when the last token was shifted. This backup is used to start an extensive search for the possible valid tokens to be replaced. This allows the developer to better understand the messages and makes it easier to select the correct token.

OMCCp uses seven different kinds of error messages for the syntax analysis and one more for the lexical analysis. The error messages displayed in this implementation are discussed below.

### 3.2.1 Erase Token

The *erase token* message occurs when the parser finds same token repeated more than once. To test if a token can be erased, the parser is run on the remaining list of tokens ignoring the current token. If the test succeeds a proper error message is displayed to the user suggesting a possible solution for erasing the repeated token [9] [11]. An example error message display is given below.

```
[../../../../testsuite/omcc_test/error5.mo:10:20-10:24:writable]
Error: Syntax error near: 'if x == 10 then then', REPLACE token with '+' or '-' or '.' or 'NOT', ERASE token 'then'
```

### 3.2.2 Insert Token

To test if a token can be inserted before the error token, the parser is run on a modified list of the remaining tokens by placing the candidate token before the error token as current token. The candidate token is selected if the test succeeds and placed in the candidate list [9] [11]. If there are items in the candidate list we display proper message to the user. An example error message is given below.

```
[../../../../testsuite/omcc_test/error3.mo:9:3-9:4:writable]
Error: Syntax error near: 'if x == 10', INSERT token 'THEN'
```

### 3.2.3 Replace Token

The replace token is similar to insert token error message. The parser is run modifying the remaining list of tokens by placing the candidate token before the error token as current token. The candidate token is selected if the test succeeds and placed in the candidate list and a proper error message is displayed to the user [9] [11].

```
[../../../../testsuite/omcc_test/error2.mo:7:1-7:6:writable]
Error: Syntax error near: 'while x <> 99 then', 'THEN', REPLACE token with 'Loop'
```

### 3.2.4 Insert Token at End

This message is used only at the end of the program, when no other token is available in the input of tokens and a non-finished acceptance state has been achieved. All the tokens are tested to verify if they can make the program to end in a valid acceptance state. If a token succeeds then the proper message is displayed to the user as a possible solution to fix the error [9] [11]. An example message is given below.

```
[../../../../testsuite/omcc_test/error6.mo:14:1-14:15:writable]
Error: Syntax error near: 'end error_test', INSERT at the End token 'SEMICOLON'
```

### 3.2.5 Merge Token

Sometimes a space can be inserted by mistake between two tokens and make a keyword appear as two separate identifier tokens. In this case the error token and the token that follows it are processed again by the Lexer with their value concatenated.

If the lexer combines them as a valid token this token is tested to see if it satisfies the test and is a valid configuration for the parser [9] [11]. If it succeeds the system displays a proper message to the user. An example error message is given below.

```
[../../../../testsuite/omcc_test/error4.mo:10:9-10:10:writable]
Error: Syntax error near: 'if x = = 10 then', MERGE tokens '=' and '=''
```

### 3.2.6 Generic Error

It is possible that no solution or candidate is found for the current error token. In these cases a generic error message is displayed to the user without any further description of the error than the location of the token.

In this situation the developer needs to fix the error token without any hint [9] [11].

### 3.2.7 Custom Error Message

While designing a grammar it is sometimes necessary to communicate to the developer that a certain transformation rule must not be used. A more clear language than presented by the error messages above should be used. For this reason the possibility of a custom error message has been introduced. Such an error message is added in the grammar rules. The use of this custom message will activate the error flag in the parser and will start the simple error recovery technique.

## 4 MetaModelica

MetaModelica is an extension of the Modelica language which can be used to model the semantics of languages, specify symbolic transformations, etc. It is based on the operational semantics language specification formalism; a rule in operational semantics becomes a case within match-expressions [6] [7].

### 4.1 Uniontype

A `uniontype` in MetaModelica is a collection of one or more record types. It can be recursive and can include other uniontypes. It is mainly used for the construction of Abstract Syntax Trees (AST) [6] [7].

Example:

```
uniontype Exp
  record INT
    Integer integer;
  end INT;
  record BINARY
    Exp exp1;
    BinOp binOp;
    Exp exp2;
  end BINARY;
end Exp;
```

### 4.2 Match Expressions

The `match` expression is similar to switch statements in C but even closer to match in functional programming languages with some extra features.

The `match` expression can return more than one value and supports pattern matching. The `match` construct contains case blocks. Each `case` can contain an equation block. The program flow tries to execute one instruction after the other in a specific local equation block. If an instruction is not executed or failed the next case is tried until a match is found. The wildcard ‘`_`’ (underscore) can be used to match all the cases [6] [7].

For example

```
function eval
  input Exp inExp;
  output Integer outInteger;
algorithm
  outInteger := match(inExp)
  local
    Integer ival, v1, v2, v3;
    Exp e1, e2, e;
  case INT(ival) then ival;
  case BINARY(e1, binop, e2)
    equation
      v1 = eval(e1);
      v2 = eval(e2);
      v3 = applyBinop(binop, v1, v2);
    then
      v3;
  case UNARY(unop, e)
    then v2=applyUnop(unop, eval(e));
  end match;
end eval;
```

In the above example we can see that the function `eval` contains one input formal parameter of type `Exp` and one output formal parameter of type `Integer` followed by the `match`-expression which tries to match any of the three cases according to the user input.

The first case results in the evaluation of `INT` record constructor node applied to an integer. The second case results in evaluation of a binary operator node `binary` to `v3`, if `v3` is the result of successfully applying the binary operator to `v1` and `v2`, which is the evaluated result of its children `e1` and `e2`. The third case results in the evaluation of unary operator node `UNARY` to `v2`.

### 4.3 List

The `List` constructor is used to create linked list structures. Lists are used in modeling of flexible variable-length collections of symbolic elements. The operand `::` is used to add an element at the front of a list (or, depending on the context, retrieve by matching) an element from the list [6] [7].

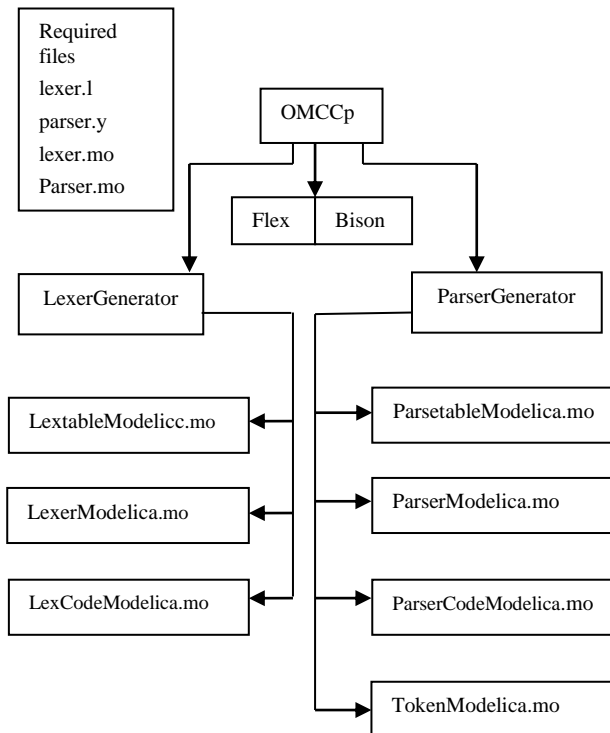

Example

```
list<Integer> a= {1,2,3};
i::a=a;
a=i::a;
```

The first line creates a list `a` of integers, the second line is used for the retrieve operation; it takes the top element 1 from the list and stores it in the variable `i` and stores the remaining list in variable `a`. The third line performs the add operation which adds an item `i` into the list `a`.

## 5 OMCCp DESIGN

The design architecture of OMCCp with the lexer and parser components is depicted in Figure 2.

**Figure 2.** OMCCp (OpenModelica Compiler-Compiler) Lexer and Parser Generator

The lexer and parser are generated based on C files generated by the tools Flex and Bison from the grammar files `lexer.l` and `parser.y`.

The generated C file contains three main parts which constitutes the lexer and parser. We can identify: a section with the transition arrays, a section with code that runs the algorithm for the lexer or parser and finally an action resolution section which contains the returns tokens actions for the lexer and reduce operation which constructs the AST.

Based on the identification of the main parts, the OMCCp design is divided into two parts namely the `LexerGenerator` and the `ParserGenerator` which are responsible for generating the necessary Lexer and Parser components in `MetaModelica`.

### 5.1 LexerGenerator

The `LexerGenerator` is the main package of the lexer generator which generates the three necessary lexer packages in `MetaModelica`, namely `LexerModelica.mo`, `LextableModelica.mo` and `LexcodeModelica.mo`.

#### 5.1.1 Lexer.mo

`Lexer.mo` is the main file which contains the calls to other functions in `Lextable.mo` and `LexCode.mo` that constitutes the lexer. The main function of this package is to load the source code file and recognize all the tokens described by the grammar.

To recognize the token the lexer.mo runs DFA (Deterministic Finite Automata) based on the transition arrays found in `Lextable.mo`. When it reaches an acceptance state it calls the function `action` in `LexCode.mo` which returns list of tokens that are input to the parser. The interface of the function which performs this operation is given below.

```

function scan
  input String fileName "input source
    code file";
  input list<Integer> program "source
    code as a stream of Integers";
  input Boolean debug "flag to activate
    the debug mode";
  output list<OMCCTypes.Token> tokens
    "return list of tokens";
end scan
  
```

#### 5.1.2 LexTable.mo

`LexTable.mo` is the source file for `Lexer.mo` which contains the transitions arrays for performing transitions to new states and finding the tokens from the input stream.

#### 5.1.3 LexCode.mo

`LexCode.mo` contains all the specific actions that a lexer performs when a token is recognized. There are three types of action a lexer can perform: *ignore* token, *return* specific token, and *switch* to another DFA.

The first action, ignore token, is performed by the lexer when a space, line feed, or block of comment has been found in the input stream. The tokens ignored by the lexer simplify the task of the parser as these tokens will not be used in the construction of the grammar.

The second action returns a specific token when a token is recognized by the lexer, the code of the action determines the tokens to be returned.

The third action is to switch from one DFA to another. This operation is performed in a few situations for example when the DFA finds a starting comment block `/*`, and all the subsequent tokens are required to be ignored or categorized as a different token, e.g. in case of determining a string. For this action a new startup state is set in the machine and new characters are processed by a different DFA than the original.

After the end of tokens is reached, i.e., ‘\*/’ then the start state returns to the original one.

## 5.2 Parser Generator

The parser generator is the main package of the parser that performs the syntax analysis of the compiler. This package generates four packages comprising the parser in MetaModelica namely TokenModelica.mo, ParserTable.mo, ParserCodeModelica.mo and ParserModelica.mo.

### 5.2.1 Parser.mo

The main function of this package is to efficiently convert the list of tokens received by the Lexer into Abstract Syntax Tree (AST). The package also contains the implementation of the LALR algorithm. For performing this task the package uses the parse table located in the package ParseTable.mo, to perform the shift-reduce action calls it uses the package ParserCodeModelica.mo. The interface of the function which starts the construction of the AST is given below.

```
function parse "realize the syntax
analysis over the list of tokens and
generates the AST tree"
input list<OMCCTypes.Token> tokens "list
of tokens from the lexer";
input String fileName "file name of the
source code";
input Boolean debug "flag to output
debug messages that explain the states
of the machine while parsing";
output Boolean result "result of the
parsing";
output ParseCode.AstTree ast "AST tree
that is returned when the result output
is true";
end parse;
```

### 5.2.2 ParseTable.mo

ParseTable.mo contains the arrays that allow the Parser package to run the Push down Automata (PDA) and perform the shift-reduce action which constructs the AST.

### 5.2.3 ParseCode.mo

The package ParseCode.mo contains the specific Reduce operations that each grammar performs when a certain rule matches the input tokens. The main function of this file is to handle the MultiTypedStack that is used by the parser to construct the AST. The MultiTypedStack handles the reduce operations requested by the LALR parsing algorithm. The MultiTyped stack contains one stack for each type found in the grammar specification and is defined in the MetaModelica language. An example interface is presented.

```
uniontype AstStack
record ASTSTACK
  list<Absyn.Exp> stackExp;
  list<String> stackString;
  list<Integer> stackInteger;
end ASTSTACK;
end AstStack;
```

When the parser finds a Shift operation it calls the 'function push' on this file which will push a String value into the stackString. During the reduce operation the parser needs to know which stack to use for each of the constructions of the AST. The way this MultiTypedStack works can be explained in the following example that presents the reduce operation, the build of the AST operation and finally a push back into the stack which builds the AST.

```
case (82,_) // #line 413
"parserModelica.y"
equation
  // reduce
  (info, skToken) =
getInfo(skToken,mm_r2[act]);
  v2Comment::skComment = skComment;
  v1Algorithm::skAlgorithm =
skAlgorithm;
  // build
  vAlgorithmItem
=Absyn.ALGORITHMITEM((v1Algorithm),SOME((v
2Comment)),info);
  // push Result
  skAlgorithmItem=
vAlgorithmItem::skAlgorithmItem;
  then ();
```

In the above case the reduction takes three items from the three different stacks and constructs an Absyn.ALGORITHMITEM object. After this it pushes the result back into the stack for the Absyn.Algorithm type called skAlgorithmItem. Another feature that can be useful for the reductions is the use of the info keyword. In the example, we can see that the instruction uses a stack called skToken to retrieve the token information.

The token information returns an info token of type Absyn.Info which contains the combined information of the first and the last token in the stack that are used for this reduction. This makes it possible for the developer to insert information about the location that can be used later in the other phases of the compiler. The package also contains another important function getAst which returns the result of AST tree to the parser. The interface of the function is given below.

```
function getAST "returns the AST built by
the parser"
input AstStackastStk aststack
"MultiTypedStack used by the parser";
output AstTree ast "returns the AST in
the final type of the tree";
end getAST;
```

### 5.2.4 Token.mo

The package contains the complete list of tokens used by the grammar with their respective codes. This file is the link between lexer and parser; it is used by both the lexer and parser to identify the tokens in the same way.

When the parser receives the token code from the lexer it performs a translation into local codes that are only used by the parser to simplify the addressing in predictive arrays. Each token is defined as an Integer-type constant. The interface of this package is presented below.

```
package TokenModelica
  constant Integer T_ALGORITHM = 258;
  constant Integer T_AND = 259;
  constant Integer T_BLOCK = 261;
  constant Integer T_CLASS = 262;
  constant Integer T_CONNECT = 263;
end TokenModelica
```

## 6 Testing

We performed testing using Modelica files from the OpenModelica testsuite. We also ensured that the tests covered full Modelica and MetaModelica grammar proving the correctness of the parser.

In the later stages of testing we also covered the ParModelica and Optimization grammars. During the testing we did not face any memory overhead problems and also measured the performance of the parser including AST building. The performance times are reasonable when compared to ANTLR. An example of sample test case of correct and an erroneous model with the respective output message are presented.

#### A Sample of correct input

```
model Circle
  Real x_out;
  Real y_out;
  Real x(start=0.1);
  Real y(start=0.1);
equation
  der(x) = -y;
  der(y) = x;
  x_out = x;
  y_out = y;
end Circle;
```

This input will generate the following success message

```
Parsing Modelica with file
../omcc_test/Test1.mo
// SUCCEED
// args:../omcc_test/Test1.mo
```

This sample of erroneous input will on the other hand generate a parse error.

```
class error_test
  int x,y,z,w;
algorithm
  while x <> 99
    x := (x+111) - (y/3);
    if x == 10 then
      y := 234;
    end if;
  end while;
end error_test;
```

This input will cause the following error message to be emitted by an OMCCp generated parser

```
Parsing Modelica with file
../omcc_test/error3.mo
[../testsuite/omcc_test/error3.mo:9:3-9:4:writable] Error: Syntax error near:
'while x <> 99', INSERT token 'LOOP'
args:../testsuite/omcc_test/error3.mo
```

The same input will cause the following error message to be emitted by an ANTLR generated parser

```
Loaded all files without error
"true
"
""
{fail() }
```

Take a look at a second erroneous sample input, an erroneous piece of MetaModelica code.

```
function add
  input Integer ininteger;
  input Integer ininteger1;
  output Integer outinteger;
algorithm
  outinteger:=
    match(ininteger,ininteger1)
    local
      Integer a,b,c;
    case(a,b)
      equation
        c=a+b;
      then
        c;
    end matchcontinue;
end add;
```

This will cause the following error message to be emitted using an OMCCp generated parser

```
Parsing Modelica with file
../omcc_test/error2.mo
[../testsuite/omcc_test/error2.mo:14:13-14:30:writable] Error: Syntax error near:
'end matchcontinue', REPLACE token with
'ENDMATCH'
args:../testsuite/omcc_test/error3.mo
```

It will cause the following error message to be emitted using an ANTLR generated parser.

```
Loaded all files without error
"true
"
""
{fail()}
```

Regard a third erroneous sample input

```
class error_test
  int x,y,z,w;
  algorithm
  while x <> 99 loop
    x := (x+111) - (y/3);
    if x == 10 then
      y := 234;
    end if;
  end while;
end error_test;
```

This will cause the following error message from an OMCCp generated parser.

```
Parsing Modelica with file
../omcc_test/error6.mo
[../../testsuite/omcc_test/error4.mo:6:9-
6:10:writable]
Error: Syntax error near:'if x = = 10
then', MERGE tokens '=' and '='
```

and this error message using an ANTLR generated parser.

```
Loaded all files without error
"true
"
""
{fail()}
```

## 6.1 Time Performance

The performance measurements for the test cases have been done using the OpenModelica test server. The models are taken from the Modelica Standard Library (MSL 3.2.1) as well as from the OpenModelica test suite. A selection of measurements is listed in the following Table 1.

**Table 1.** Time measurement of OMCCp and ANTLR generated parsers on a set of test models.

Model	Size	No of Tokens	OMCCp (time ms)	ANTLR (time ms)
Dcmotor	2kB	172	3.1	0.45
Influenza	4kB	642	10.4	1.10
Test1	26kB	8443	84.3	6.90
Icon	42kB	9234	179.7	8.68
SIunit	94kB	14330	303.8	18.57
Electrical/Digital	366kB	71117	1576	93
Electrical/Machine	763kB	143505	3202	158
Test2	1MB	214617	4681.8	254
Total	11MB	2078841	51362	2704

We can see that the ANTLR generated parser is about 5 to 16 times faster than OMCCp including AST building. The OpenModelica implementation of an ANTLR generated parser is extremely fast. The OMCCp parser performance is comparable to typical non-optimized parser generators.

The OMCCp generated parser is roughly 16 times slower than ANTLR for the very large Modelica models like `Total.mo` which contains the whole Modelica standard library 3.2.1 of 11 MB, but in general for smaller test cases the parser is only 6 times slower.

From the table we can also see that the OMCCp parser does not scale as well in the case of large models compared to ANTLR. Even though the ANLTR parser is faster, the OMCCp tool has several advantages compared to ANTLR. One should also note that the current implementation of OMCCp was not optimized and its performance can be further improved.

During testing we found that the OMCCp tool did not have any memory overhead problems when parsing a large number of test cases in a single attempt whereas the ANTLR parser had higher memory overhead when many test cases were parsed in a single attempt. Moreover, the OMCCp tool has better error handling features compared to the ANTLR tool, which makes it easier to use.

### 6.1.1 Performance Graph

**Figure 3:** Graph representation of time performance of OMCCp with ANTLR

From the above graph we can see that the OMCCp parser keeps its timing performance close to that of ANTLR for a certain number of tokens recognized by the lexer, but when the number of tokens increases the performance gap increases between the tools.

Still the OMCCp tool has good performance when parsing grammars of size less than 100kB, with times of under a second. One of the reasons that the OMCCp is slower is that garbage collection is used in Meta-Modelica whereas in ANTLR the memory allocation/de-allocation is manually programmed.

## 7 Conclusion

In this paper we have presented a fully implemented OMCCp lexer and parser generator integrated with MetaModelica as a semantic specification language in the new bootstrapped OpenModelica compiler.

We have tested this tool on number of small languages as well as on the large Modelica grammar. The generated parsers offer good error handling and comprehensive error messages to the user. OMCCp can also be used as a parser generator for any language for which an LALR(1) grammar is available. The associated language semantics can be specified using MetaModelica.

The generated parsers are still a bit slow for production usage on large programs but we expect to improve the performance by further tuning.

# Nonlinear inverse models for the control of satellites with flexible structures

Matthias J. Reiner    Johann Bals

German Aerospace Center (DLR), Institute of System Dynamics and Control  
82234 Wessling, Germany, {Matthias.Reiner, Johann.Bals}@DLR.de

## Abstract

Nonlinear inverse dynamic models can be utilized in various parts of advanced model-based control system design: reference trajectory optimization, feed-forward control and feedback linearization [35]. In this paper, a new synthesis approach for nonlinear inverse dynamic models of satellites with flexible structures is presented. For satellite configurations with unstable zero dynamics, a stable inverse model approximation is proposed which has been successfully applied to robots with flexible bodies.

This inverse modeling approach is part of the newly developed DLR Space Systems Library for object-oriented modeling and simulation of satellites and launchers in a detailed space environment. For satellites with flexible structures, the library provides models for normal simulation mode and the necessary tools to directly generate approximate inverse models.

In this paper, trajectory optimization is shown to be an important use case for inverse dynamic models. By inversion based reformulation of the trajectory optimization problem, the optimal reference motion of the control system can be determined in a reliable and efficient way.

*Keywords:* satellite modeling; nonlinear inverse model; trajectory optimization; flexible structure

## 1 Introduction

The Space Systems Library (SSL) was built to develop advanced control systems for satellites / spacecraft with flexible structures. In particular, one goal of this library is to generate nonlinear inverse models for the controller. The library contains state-of-the-art Low Earth Orbit (LEO) space environment models and components. It was implemented in the Modelica modeling language [23].

The theory of satellite dynamics is well understood and many important aspects of spacecraft modeling

are described in publications such as [24]. A wide range of satellite simulators exist [3, 2, 11, 5, 36] that are able to accurately simulate a satellite in orbit.

There also exist simulators based on the Modelica modeling language. The authors made use of the advantages of using the Modelica language for the implementation and the inversion of rigid satellites [29]. In addition, several related publications such as [30, 20, 19] describe the simulation of satellites in detail. Satellites with flexible appendages were considered in [33]. Many important aspects of spacecraft modeling are already covered in these publications and promising results were reported by these authors.

The Space Systems Library was developed to implement nonlinear inverse models of satellites with flexible structures, such as solar panels, that cannot be easily implemented within existing simulators. Having direct access to all component equations from the SSL allows the successful implementation of algorithms from recent results obtained in the field of robotics regarding the inversion of flexible multi-body systems and trajectory optimization based on inverse models [32, 31].

The new DLR internal library builds upon the Modelica Standard Library [23], and especially the Modelica MultiBody Library [25], as well as the DLR FlexibleBodies Library [12], DLR Visualization Library [1] and the DLR Optimization Library [27]. The SSL combines their capabilities to achieve a wide range of possible applications, ranging from visualization of space missions to high accuracy simulations, optimizations and development of control systems for satellites with flexible structures.

The objective of this paper, apart from introducing the SSL, is to demonstrate its capabilities by modeling a near Earth satellite based on the TET-1 prototype [8], which is part of the FireBird mission – a mission of the German Aerospace Center (DLR) for fire reconnaissance [4, 16]. The modeling of the satellite is described in section 3.

The satellite is modeled with flexible solar panels<sup>1</sup>. From the nonlinear (direct) satellite model, an inverse model is derived (sec. 4). This inverse model is used to calculate optimal trajectories for a reorientation maneuver of the satellite using the reaction wheels under constraints (sec. 5) and can also be used as a feed-forward controller.

## 2 The Space Systems Library

The SSL enables object-oriented, acausal, and equation-based modeling of space systems dynamics and its corresponding environments. This in turn allows controller design and verification, as well as development of path planning and other algorithms.

**The Space Systems world model** The default world model of the Modelica MultiBody Library [25] is exchanged by a new world model which is compatible with the default world model. It offers additional options and methods for space environment simulations. The world model handles the global simulation time that is used to calculate planet positions and various transformations. The initial time can be given in calendar- or Julian date format. The latter is also implemented internally as time format. The basis coordinate system is chosen to be the Earth Centered Inertial (ECI) coordinate system, which is suitable for near earth satellite simulations. The world model offers a connector and transformation for the Earth Centered Earth Fixed (ECEF) coordinate system, which is useful for the simulation of objects on earth, like emitter stations. The transformation from ECI to ECEF coordinate system is computed as described in [24, 15]. This calculation also considers the difference in seconds between Universal and Universal Coordinated Time (leap seconds,  $t_{UT1-UTC}$ ) that has to be given as an initial value and can be taken from tabular data [37].

**Gravity acceleration computation** The gravity acceleration  $g_0 \in \mathbb{R}^3$  plays a very important role for the simulation of satellites. Hence, multiple gravity models of different complexity were implemented. The most precise model implemented is the EGM96 gravity model [18]. A computational efficient approximation of this model was implemented, which uses terms of up to the second degree of the zonal harmonic coefficients of the gravitational potential. In addition,

moon and sun gravities have been included, considering them as important perturbation factors. These are modeled as point gravity [24]. Although newer, more advanced gravity models exist, the accuracy of the chosen models is sufficient for our multi-body approach that focuses on short term simulations.

**Gravity gradient torque** The gravity gradient torque is modeled as a torque  $\tau_a$  that acts on the frame  $a$  (position  $r_{0,a} \in \mathbb{R}^3$  and orientation  $R_a \in \mathbb{R}^{3 \times 3}$ . The index  $a$  is used to describe a generic frame, which is instantiated for every object) to which it is connected. This frame should be connected to the center of mass of the body in consideration. The torque is caused by the mass distribution of the body in consideration, and depends on the inertia tensor  $I \in \mathbb{R}^{3 \times 3}$  as follows.

$$\tau_a = \left( R_a \cdot g_0(r_{0,a}, t_J) \frac{3}{\|r_{0,a}\|} \right) \times \left( I \cdot R_a \frac{-r_{0,a}}{\|r_{0,a}\|} \right) \quad (1)$$

In eq. (1), the gravity acceleration vector  $g_0 \in \mathbb{R}^3$  is a function of the position  $r_{0,a}$  and the Julian date  $t_J$  (to compute planet positions). See [17] for more details.

**Solar radiation pressure** The effect of the solar radiation pressure  $p_\odot$  is modeled as a force element  $f_{sp} \in \mathbb{R}^3$  that acts on the element to which it is connected. Shadows of the moon and sun are considered using a cylindrical shadow model. The models are implemented as proposed in [24].

**Atmospheric drag** The atmospheric drag is caused by friction with the atmosphere depending on the height of the satellite above the Earth. Like the radiation pressure, it is modeled as a force and torque element acting on the attached body which should be located at the center of pressure.

The density  $\rho(\lambda, \phi, h, t_J)$  of the atmosphere is computed using the NRLMSISE-00 atmospheric density model [28]. The density  $\rho$  depends on the longitude  $\lambda$ , latitude  $\phi$  and height above earth  $h$ , that can be computed from  $r_{0,a}$ , as well as the actual Julian date  $t_J$ . The drag force  $f_a \in \mathbb{R}^3$  and torque  $\tau_a \in \mathbb{R}^3$  can be computed using eq. (2).

$$v_{rel} = \dot{r}_{0,a} - \omega_\oplus \times r_{0,a} \quad (2a)$$

$$f_a = -R_a \frac{1}{2} c_d A_{ad} \rho \|v_{rel}\| v_{rel} \quad (2b)$$

assuming  $\|v_{rel}\| \neq 0$  (otherwise  $\tau_a = 0$ ):

$$\tau_a = R_a \frac{1}{2} c_d A_{ad} \rho \|v_{rel}\|^2 \left( \frac{v_{rel}}{\|v_{rel}\|} \times (R_a s_{cp}) \right) \quad (2c)$$

<sup>1</sup>The term "flexible satellite" will be used hereafter as a shorthand notation.

In eq. (2),  $\omega_{\oplus} \in \mathbb{R}^3$  is the earth angular velocity,  $c_d$  is the drag coefficient,  $A_{ad}$  is the affected area (which can depend on  $R_a$ ) and  $s_{cp} \in \mathbb{R}^3$  is the vector from the center of pressure to the center of mass, all resolved in the attached frame  $a$ .

**Geomagnetic field** The geomagnetic field can be computed at a desired frame (position  $r_{0,a}$ ) by a geomagnetic field component, using the US/UK World Magnetic Model [22]. The model provides a magnetic field vector  $B_m(\lambda, \phi, h, t_J) \in \mathbb{R}^3$  that depends on the longitude  $\lambda$ , latitude  $\phi$  and height above earth  $h$ , which can be computed from  $r_{0,a}$  and the Julian date  $t_J$ .

**Variable mass systems** The effects of variable mass systems are very important for the modeling of launchers but their consideration can also be necessary for satellites that use gas thrusters, if high precision for the simulation is required. If mass flow  $\dot{m} \in \mathbb{R}$  is small, variable mass is usually neglected. Effects of thrusters and jets together with their tanks can be modeled as variable mass systems.

For the SSL, variable mass systems were implemented based on [9, 10] using the concept of a variable mass cylinder with different models of fuel burning. The cylinder represents the fuel or gas tank that is directly attached to the nozzle (of the thruster or jet).

### 3 The satellite model with flexible structures

The satellite model consists of flexible structures that are modeled as modal bodies as described in [12]. They are based on the definition of Standard Input Data (SID) as defined in [38] as well as rigid bodies and powertrain elements. The equations of motion of each flexible part  $i$  are given in eq. (3). The  $\tilde{(\cdot)}$  operator is used to generate a skew-symmetric matrix of a vector.

$$\begin{pmatrix} m_i I_3 & & \text{sym.} \\ m_i \tilde{d}_{CM,i}(q_i) & \Theta_i(q_i) & \\ C_{t,i}(q_i) & C_{r,i}(q_i) & M_{e,i} \end{pmatrix} \begin{pmatrix} a_{R,i} \\ \dot{\omega}_{R,i} \\ \dot{q}_i \end{pmatrix} + \begin{pmatrix} 2\tilde{\omega}_{R,i} C_{t,i}^T(q_i) \dot{q}_i + \tilde{\omega}_{R,i} \tilde{\omega}_{R,i} d_{CM,i}(q_i) \\ G_{r,i}(\dot{q}_i) \tilde{\omega}_{R,i} + \tilde{\omega}_{R,i} \Theta_i(q_i) \omega_{R,i} \\ G_{e,i}(\dot{q}_i) \tilde{\omega}_{R,i} + O_{e,i}(q_i) \Omega(\omega_{R,i}) \end{pmatrix} + \begin{pmatrix} 0 \\ 0 \\ K_{e,i} q_i + D_{e,i} \dot{q}_i \end{pmatrix} = \begin{pmatrix} h_{t,i} \\ h_{r,i} \\ h_{e,i} \end{pmatrix} \quad (3)$$

The meaning of the symbols in eq. (3) are listed in table 1. The file of a flexible body (SID) can be ob-

Table 1: SID abbreviations	
$a_R, \omega_R \in \mathbb{R}^3$	acceleration of the ref. frame
$q \in \mathbb{R}^{n_e}$	modal amplitudes
$m \in \mathbb{R}$	body mass
$I_3 \in \mathbb{R}^{3 \times 3}$	identity matrix
$d_{CM}(q) \in \mathbb{R}^3$	position of center of mass
$\Theta(q) \in \mathbb{R}^{3 \times 3}$	inertia tensor
$C_t(q) \in \mathbb{R}^{n_e \times 3}$	inertia coupling mat. (trans.)
$C_r(q) \in \mathbb{R}^{n_e \times 3}$	inertia coupling mat. (rot.)
$k_{\omega}(\omega_R, q, \dot{q}) \in \mathbb{R}^{3+n_e}$	gyro. and centrifugal forces
$\Omega(\omega_R) \in \mathbb{R}^6$	components of $\omega_R$

$G_r(\dot{q}) \in \mathbb{R}^{n_e \times 3}$	gyroscopic matrix (rot.)
$O_e(q) \in \mathbb{R}^{n_e \times 6}$	centrifugal matrix (modal)
$h(q) \in \mathbb{R}^{3+n_e}$	external forces
$M_e \in \mathbb{R}^{n_e \times n_e}$	modal mass matrix
$K_e \in \mathbb{R}^{n_e \times n_e}$	modal stiffness matrix
$D_e \in \mathbb{R}^{n_e \times n_e}$	modal damping matrix

tained from an FEM-analysis (e.g. using ANSYS® or ABAQUS® in combination with SIMPACK®) directly from CAD and material data of the component. In the modal reduction,  $n_e$  modes are selected and the required data to calculate eq. (3) is stored in the SID file. The flexible bodies can be combined with other flexible and rigid bodies to model the structural dynamics of the satellite.

The reaction wheels are driven by a motor together with a powertrain including friction. Furthermore, most powertrains used in today's satellites are very stiff. Future satellite designs may incorporate more lightweight constructions with elastic effects in the powertrains, in combination with more powerful and agile motors, as in robotics today. For this reason nonlinear elasticity between the motor and the reaction wheel disk can be taken into account. The elasticity can result from the material of the drive shaft or due to the construction of the coupling. By combining one dimensional models of the powertrain with three dimensional inertia and mass elements, computational efficient models can be designed by using mounting and rotor elements as described in [34]. To model a powertrain in a way which can also be used to generate inverse models is described in [32, 31]. It consists of approximate friction and nonlinear elasticity models that have strictly monotonic characteristics.

Using the components of the library, a detailed mechanical satellite model can be built. The benchmark model used here is a satellite model which is based

Figure 1: Animation of the satellite with the SSL.

on the TET-1 prototype [8], with slightly exaggerated elasticities, in order to demonstrate the capabilities of the library and future lightweight satellite designs. Three solar panel elements have been modeled as modal bodies. These have been generated from CAD data, a subsequent FEM-analysis, followed by a modal reduction and finally obtaining an SID model. The main body of the satellite is modeled as a rigid body because it is considerably less flexible than the solar panels. Fig. 1 shows an animation of the satellite generated with the SSL. Three reaction wheels mounted at the main satellite body are modeled as rigid bodies representing flywheels. They are connected to one-dimensional (rotational) flexible powertrains with friction and first order motor dynamics. The gyroscopic torques of the one-dimensional powertrain elements are considered in the model by using the mounted rotor elements as described in [34]. The gravity  $g_0$  which is acting on the rigid and flexible bodies is calculated using the gravity model, which is defined by the (global) satellite world model. Additional force and torque elements are connected to the satellite to account for the solar radiation pressure and atmospheric drag as well as the gravity gradient torque, described in sec. 2.

## 4 Inversion of a structural elastic satellite model

On the top level, a satellite dynamics model has the structure as shown in the top half of fig. 2.

The motor currents  $I_m$  are used to drive the reaction wheels of the satellite, from which in turn the rotation of the satellite is determined by the solution of a differential-algebraic equation system. In particular, the angular velocity  $\omega_{ACS}$  of the central satellite frame

Figure 2: Top level view of direct and inverse satellite model.

Figure 3: Two degree of freedom control of the satellite motors. With feed-forward controller  $\Sigma_{ff}$ , feed-back controller  $\Sigma_{fb}$  and satellite  $\Sigma$ .

is computed, it will be referred to as the ACS-frame (Attitude Control System). This computation is a standard task of satellite simulators.

For advanced control systems, the inverse of this model is needed, as shown in the lower half of fig. 2. The previously given motor currents  $I_m$  shall now be computed from the desired angular velocity  $\omega_{D,ACS}$ . The nonlinear inverse model is based on the satellite model described in section 3. The basis for the inversion of a nonlinear (Modelica) model are index-reduction techniques using the algorithm of Pantelides. The index reduction method [26, 21] allows to choose which equations have to be used to generate a DAE of (at most) index one. All Modelica simulators support this or similar algorithms and automatically perform the inversion. However, both the generation of the inverse model, as well as the numerical computation may fail, if the underlying model does not fulfill certain requirements. Especially, the system must be smoothly continuously differentiable up to the necessary order of differentiation that is determined by the algorithm of Pantelides.

Such a nonlinear inverse model can be, for example, used as feed-forward controller  $\Sigma_{ff}$  for the inner control loop, see fig. 3. An additional outer feedback control loop based on the satellites star tracker would be needed to achieve stationary accuracy of the satellite. For a rigid satellite with rigid powertrains without motor dynamics  $\omega_{D,ACS}$  and the equations of motion have to be continuous differentiable at least once so that the equations for the inverse model can be solved via the

Figure 4: Setup of the approximate inverse satellite model with flexible solar panels and powertrains. The global world model provides the gravity model and simulation time. The environment causes forces and torques on the satellite as described in section 2. Because the environment effects can depend on the states of the satellite, they have to be included for both parallel models of the satellite (I & II).

algorithm of Pantelides. For a satellite with flexible structures and flexible powertrains and first order motor dynamics, as described in section 3,  $\omega_{D,ACS}$  as well as the equations of motion have to be differentiable at least three times. In practice, this should be increased by at least one order to avoid non-differentiable motor currents. If these higher order derivatives of  $\omega_{D,ACS}$  are not available, a low-pass filter can be used to approximately compute  $\omega_{D,ACS}^*$  and its derivatives (see [35, 32, 31]). This is a reason why exact sticking friction cannot be used as part of the inverse model and an approximation has to be used. For components that use non differentiable (e. g. tabular) data like the NRLMSISE-00 atmospheric density model [28] the derivatives have to be either approximated or neglected. This can be achieved in Modelica by using user-defined derivative-functions instead of automatic symbolic differentiation.

It is also necessary that the inverse model is stable. For a linear model this means that the model to be inverted has no (transmission-) zeros in the right half of the complex plane. For the nonlinear model this means that the zero dynamics has to be stable. For highly nonlinear models it is usually very difficult or even impossible to calculate the zero dynam-

ics analytically (e. g. using methods described in [13] that involve solving partial differential equations). Often, the only practical way is to calculate linearizations of the nonlinear model to verify the stability of the (transmission-) zeros.

One typical reason for unstable (transmission-) zeros for systems with flexible structures is the non-collocation of inputs (actuators) and outputs (sensors) of the system. For structural elastic robots this can be the case if motor torques are chosen as output and the robot tip position is chosen as input of an inverse model [32]. The same problem is also possible for flexible satellites, e. g. if the main satellite body attitude should be controlled by actuators that are positioned on a flexible mounting. In general, in order to achieve a stable inverse model of a flexible satellite, approximations must be used, as explained in sec. 4.1, because the exact inverse model is unstable. A first step for the construction of the satellite's inverse model is the definition of a base ACS-frame. The desired angular velocity  $\omega_{D,ACS}$  of the satellite will be given with respect to this frame. A good choice for the ACS-frame is either the center of mass of the satellite, or the tip-position of an important on-board instrument of the satellite, e. g. a mounted camera or sensor. This frame is imposed as a root frame according to the Modelica MultiBody Library definition [25]. Hence, the orientation  $R_a \in \mathbb{R}^{3 \times 3}$  as well as the angular velocity  $\omega_a$  of the frame are computed consistently. In addition, the kinematic tree of the satellite is rooted in this frame, although the frame itself can be moving. This is necessary to handle overdetermined DAEs with symbolic transformation techniques in a way that is used in the Modelica MultiBody Library (for further details see the appendix in [25]). The translation of the ACS-frame is not restricted and it moves according to the external forces and the gravity, which act on the bodies connected to it. This results in a hybrid forward/inverse model corresponding to the translation and orientation. The model inversion is done by using the desired angular velocity  $\omega_{D,ACS}$  as input for the local angular velocity of the ACS-frame  $\omega_a$ , starting from a defined angular velocity  $\omega_{a,0}$  and orientation. The original input for the forward model  $I_m$ , which is the current of the three reaction wheels, is chosen as the new output for the inverse model. The computation of the required angular velocity  $\omega_{D,ACS}$ , for a specific maneuver, will be described in section 5.

The ACS-frame is connected to the satellite body with its actuators. The desired angular velocity  $\omega_{D,ACS}$  of the ACS-frame is achieved by adding a set of equa-

tions to force the angular velocities to the desired values (using Modelica inverse block constraints). This results in three additional equations for the calculation of the torques of the attached torque wheels  $\tau_w \in \mathbb{R}^3$ . The resulting equations for the ACS-frame model are given in eq. (4).

$$R_a = f_{rot}(\phi_{ACS}) \quad (4a)$$

$$\omega_a = f_{\omega}(\phi_{ACS}, \dot{\phi}_{ACS}) = \omega_{D,ACS} \quad (4b)$$

$$\tau_a = -\tau_w \quad (4c)$$

In eq. (4),  $f_{rot}$  and  $f_{\omega}$  are functions to calculate the transformation matrix  $R_a$  and local angular velocity  $\omega_a$ . Although the values of the Cardan angles  $\phi_{ACS}$  can jump, the internal representation of the orientation is calculated using rotation matrices that remain continuous and show no singularities (see [25] for implementation details). The ACS-frame is forced to move along the desired orientation and the required torques are generated by the attached reaction wheels via  $\tau_w$  from which the motor currents  $I_m$  can be computed by inversion of the elastic powertrain and first order motor dynamics [32, 31]. This is only possible if the reaction wheels are mounted in such a way that they can generate the required torque vector  $\tau_w$ . Otherwise the equation system will not be solvable (singular). If more than three reaction wheels are used, a torque allocation algorithm has to be implemented in addition.

#### 4.1 Approximation of the deformation of flexible structures of an inverse satellite model

For satellites with flexible structures, depending on the location of the ACS-frame, the exact inverse system can be unstable, and therefore not useful for a control system. This can be checked by calculating the transmission-zeros of the linearized system. If they have a positive real part, the inverse model will be unstable. They can be caused by the combination of flexible structures and the chosen ACS-frame location. In addition, the exact inversion of the equations of motion of flexible structures with weak damping can lead to numerical instability and stiff systems. A solution for this problem is to obtain an approximation of the elastic deformations for the inverse satellite model. Our method is based on a quasi-static approach using two parallel models. A similar method was already successfully implemented for the inversion of flexible robot arms in [32, 31]. Starting points are flexible bodies modeled after eq. (3) from an SID file. In the first

model, quasi-static approximations for the elastic deformation  $\hat{q} \in \mathbb{R}^{n_e}$  are calculated. In the second model, these deformations are used as input for the flexible parts and the resulting forces are re-calculated. Figure 4 shows an overview for the setup of the inverse satellite model with flexible solar panels and powertrains. For the first of the two parallel models, the equations of motion for a flexible body are given in eq. (5). The index  $i$  for each component is omitted here.

$$\begin{pmatrix} mI_3 & sym. \\ m\tilde{d}_{CM}|_{q=0} & \Theta|_{q=0} \end{pmatrix} \begin{pmatrix} a_R^{(r)} \\ \dot{\omega}_R^{(r)} \end{pmatrix} \quad (5a)$$

$$+ \begin{pmatrix} \tilde{\omega}_R^{(r)} \tilde{\omega}_R^{(r)} d_{CM}|_{q=0} \\ \tilde{\omega}_R^{(r)} + \tilde{\omega}_R^{(r)} \Theta|_{q=0} \omega_R^{(r)} \end{pmatrix} = \begin{pmatrix} h_t^{(r)} \\ h_r^{(r)} \end{pmatrix} \quad (5b)$$

$$\begin{aligned} h_e^{(r)} &= C_t|_{q=\hat{q}} g_{ref}^{(r)} \\ &+ \sum_j^{n_{node}} \left( \Phi_{m,j}^T|_{q=\hat{q}} f_{ref,j}^{(r)} + \Psi_{m,j}^T|_{q=\hat{q}} \tau_{ref,j}^{(r)} \right) \\ &= C_t|_{q=\hat{q}} a_R^{(r)} + C_r|_{q=\hat{q}} \dot{\omega}_R^{(r)} + G_e|_{q=\hat{q}} \omega_R^{(r)} \\ &\quad + O_e|_{q=\hat{q}} \Omega(\omega_R^{(r)}) + K_e \hat{q} + D_e \dot{\hat{q}} \end{aligned}$$

The notation  $(\cdot)^{(r)}$  denotes variables calculated using the assumption that forces which cause the deformations can be approximated by neglecting elastic deformations (quasi-static). This also leads to a simplification of terms that would normally depend on the elastic deformation  $q$ . Therefore, the flexible structural parts are calculated as rigid bodies and approximations for the deformations  $\hat{q}$  are calculated using eq. (5) in the first parallel model. To get a stable approximation, terms for the second derivative with respect to time involving  $\ddot{\hat{q}}$  are neglected in eq. (5), so that a nonlinear first order differential equation (that is linear in its highest derivative  $\dot{\hat{q}}$ ) is obtained to approximate  $q$  in the inverse model.

The approximation  $\hat{q}$  is used as input for the second (parallel) inverse satellite model. In the second model, the approximations for  $\hat{q}$  are used to recalculate all forces and positions. This is necessary because the resulting deformations change the forces and torques that act on the connected bodies. The equations of motion of the flexible parts in the second model are given

in eq. (6).

$$\begin{pmatrix} mI_3 & m\tilde{d}_{CM}^T|_{q=\hat{q}} & C_t^T|_{q=\hat{q}} \\ m\tilde{d}_{CM}|_{q=\hat{q}} & \Theta|_{q=\hat{q}} & C_r^T|_{q=\hat{q}} \end{pmatrix} \begin{pmatrix} a_R^{(II)} \\ \dot{\omega}_R^{(II)} \\ \ddot{\hat{q}} \end{pmatrix} + \begin{pmatrix} 2\tilde{\omega}_R^{(II)}C_t^T|_{q=\hat{q}}\dot{\hat{q}} + \tilde{\omega}_R^{(II)}\tilde{\omega}_R^{(II)}d_{CM}|_{q=\hat{q}} \\ G_m|_{\dot{q}=\dot{\hat{q}}}\tilde{\omega}_R^{(II)} + \tilde{\omega}_R^{(II)}\Theta|_{q=\hat{q}}\omega_R^{(II)} \end{pmatrix} = \begin{pmatrix} h_t^{(II)} \\ h_r^{(II)} \end{pmatrix} \quad (6)$$

Because the approximation of the modal amplitudes  $\hat{q}$  are used directly as input, equations for the modal forces  $h_e$  are not necessary in eq. (6). In this equation, the second derivative  $\ddot{\hat{q}}$  is again considered. In general, if the flexible parts are connected to each other, it is also possible that the reference accelerations and velocities as well as the external forces change, so they are denoted with the notation  $(.)^{(II)}$ .

This approximation is valid for small deformations and smooth reorientation maneuvers without extreme external forces and can always be calculated where otherwise no solution could be found (because the exact inverse model would be unstable, depending on the chosen ACS-frame location). If the approximation is sufficient for a specific application can be verified by simulating the approximate inverse model in combination with the original forward model and looking at the resulting error in the calculated torques and deformations. If the resulting error is within the mission tolerance, the approximation can be used. A feedback controller can minimize the remaining error. A typical result for the approximation shows fig. 5, where the first bending mode of an outer solar panel is compared to the resulting first mode of the solar panel without approximation, when using the computed motor currents  $I_m$  as feed-forward command (without any feedback controller). The approximation  $\hat{q}_1$  follows  $q_1$  closely, but a residual vibration remains at the end of the movement which results from the (stable) first order approximation for the modal amplitude in eq. (5). This vibration can be further damped by a feedback-controller.

The resulting state  $x_{inv}$ , input  $u_{inv}$  and the output  $y_{inv}$  for the inverse model model setup of fig. 4 is given in eq. (7). The state of the inverse model consists of the states of several subsystems. The states of the ACS-frame  $x_{ACS}$ , the three powertrains  $x_{PT}$  and the states of the approximation of the modal amplitudes  $\hat{q}_s$  for the three solar panel elements. They are modeled with  $n_e = 3$  modes for each panel. For the powertrains the flexibility of the connection to the reaction wheels is modeled as spring damper systems (states

Figure 5: Comparison of the first mode (normalized) between approximation  $\hat{q}_1$  and resulting mode  $q_1$ .

$\phi_{rel,PT}, \dot{\phi}_{rel,PT}$ ). Because the parallel model setup is used, two sets of states (I & II) are needed for  $x_{ACS}$  and  $x_{PT}$ .

$$x_{inv} = \left( x_{ACS}^{(I)}, x_{ACS}^{(II)}, x_{PT}^{(I)}, x_{PT}^{(II)}, \hat{q}_s \right)^T \in \mathbb{R}^{51} \quad (7a)$$

$$u_{inv} = \omega_{D,ACS} \in \mathbb{R}^3, y_{inv} = I_m \in \mathbb{R}^3 \quad (7b)$$

with:

$$x_{ACS} = (\phi_{ACS}, r_{0,ACS}, v_{0,ACS}) \quad (7c)$$

$$x_{PT} = (\phi_m, \dot{\phi}_m, \phi_{rel,PT}, \dot{\phi}_{rel,PT}) \quad (7d)$$

If the input for  $u_{inv}$  is not differentiable, a filter has to be used and the states of the filter are then also part of  $x_{inv}$ . Simulation results showed that the inverse satellite model can be used to accurately calculate the required motor currents and estimate the deformations of the flexible parts using the new approximation method for typical trajectories.

## 5 Computing optimal trajectories using inverse satellite models

The goal of the attitude trajectory optimization is to find optimal motor currents  $I_m \in \mathbb{R}^3$  reorienting the satellite from a starting orientation  $Q_{D,0}$  (using a unit quaternion representation  $Q_D \in \mathbb{R}^4$ ) at time  $t_0$  to a desired end orientation  $Q_{D,f}$  at time  $t_f$ . Using a forward model of the satellite with flexible structures, this op-

timization problem is defined by eq. (8).

$$\min \left\{ \xi_t t_f + \xi_I \sum_{i=1}^3 \left( \int_{t_0}^{t_f} |I_{m,i} \dot{\phi}_{m,i}| dt \right) \right\} \quad (8a)$$

with:

$$F(t, x, \dot{x}, z, u) = 0, x(t_0) = x_0, t \in [t_0, t_f] \quad (8b)$$

$$Q(x_0, z_0, t_0) = Q_{D,0} \quad (8c)$$

constrained by:

$$|\dot{\phi}_m| \leq \dot{\phi}_m^{max} \quad (8d)$$

$$Q(x, z, t) = Q_{D,f} \text{ for } t \geq t_f \quad (8e)$$

with control function:

$$u_c(t) = I_m(t) \in \mathbb{R}^3, |I_{m,i}| \leq I_m^{max} \quad (8f)$$

The chosen criteria allows the optimization of time- or energy-optimal attitude trajectories (or mixtures). The term  $F(t, x, \dot{x}, z, u) = 0$  represents the nonlinear satellite model in implicit DAE form where  $t$  denotes the time,  $x$  the states,  $u$  the inputs (unknown motor currents  $u = I_m$ ) and  $z$  the algebraic variables of the system. The scalar factors  $\xi_t, \xi_I \in \mathbb{R}_+$  are used to weight the criteria for the optimization. The factor  $\xi_t$  weights the resulting end time  $t_f$  for which the end orientation  $Q_{D,f}$  is reached, while  $\xi_I$  is a weight for the energy criteria and  $\dot{\phi}_m \in \mathbb{R}^3$  are the motor angular velocities for the three motors.

The optimization problem in eq. (8) is difficult to solve directly because of the large solution space for  $I_m(t)$  in combination with the strict constraint for the end orientation. By using an inverse satellite model with flexible structures from section 4 and a parameterization of the orientation, the optimization problem can be greatly simplified. The desired orientation is restricted to a path  $Q_D(s(t))$  which is calculated by using a spherical linear quaternion interpolation (SLERP, see [6]) along a scalar path parameter  $s(t) \in [0, 1]$ . This results in an interpolation from the starting orientation  $Q_{D,0} = Q_D(s=0)$  to the end orientation  $Q_{D,f} = Q_D(s=1)$ . The desired angular velocity  $\omega_{D,ACS}$  for the ACS-frame which is used as input for the inverse satellite model can be calculated using eq. (9) where  $\omega_0$  is the initial angular velocity of the ACS-frame resolved in the ECI-frame and  $q_i$  are scalar elements of  $Q_D$ .

$$\omega_{D,ACS} = 2 \begin{pmatrix} q_4 & q_3 & -q_2 & -q_1 \\ -q_3 & q_4 & q_1 & -q_2 \\ q_2 & -q_1 & q_4 & -q_3 \end{pmatrix} \dot{Q}_D \quad (9)$$

$$+ 2((q_4 q_4 - 0.5)\omega_0 + ((q_1, q_2, q_3)^T \omega_0)(q_1, q_2, q_3)^T - q_4((q_1, q_2, q_3)^T \times \omega_0))$$

The resulting optimization problem is described in

eq. (10).

$$\min \left\{ \xi_t t_f + \xi_I \sum_{i=1}^3 \left( \int_{t_0}^{t_f} |I_{m,i} \dot{\phi}_{m,i}| dt \right) \right\} \quad (10a)$$

with:

$$F(t, x, \dot{x}, z, u_c) = 0, x(t_0) = x_0, t \in [t_0, t_f] \quad (10b)$$

constrained by:

$$|\dot{\phi}_m| \leq \dot{\phi}_m^{max} \quad (10c)$$

$$|I_{m,i}| \leq I_m^{max} \quad (10d)$$

$$\int_0^{t_f} u_c(t) dt = s(t_f) = 1 \quad (10e)$$

with control function:

$$u_c(t) = \dot{s}(t) \in \mathbb{R}_+ \quad (10f)$$

$$u_c(t_0) = u_c(t_f) = \dot{u}_c(t_0) = \dot{u}_c(t_f) = 0 \quad (10g)$$

To achieve a finite optimization problem, the infinite possibilities for the path parameter  $s(t)$ , given by the integration over the control function  $u_c(t)$ , have to be limited by using an appropriate parameterization. This is performed by using a B-spline [7] of order  $n_s = 3$  to parameterize  $u_c(t)$ . Using inverse models in combination with a path parameter  $s(t) \in [0, 1]$  inside the optimization offers great advantages over a direct optimization of the motor currents:

- The number of necessary tuners<sup>2</sup> is much smaller. Instead of having to parametrize all three motor currents  $I_m(t)$ , only one scalar function  $u_c(t)$  has to be parametrized.
- The optimization does not have to stabilize the system like a controller. Using the desired path  $Q_D(s)$  as input for the inverse model results in reaching  $Q_{D,f}$  exactly.

The equality condition  $s(t_f) = 1$  can still be difficult to achieve for optimization algorithms. There are two possible ways to overcome this. One possibility is to avoid the equality condition by using an additional criteria for the optimization in the form of eq. (11).

$$(s(t_f) - 1)^2 \rightarrow \min \quad (11)$$

However, this can lead to an unacceptable error in the end-orientation  $Q_{D,f}$ . A better way to avoid the equality condition is to directly reshape the B-spline control vector  $d_c$  each time the tuner vector is modified by the optimization algorithm. The modified vector is called

<sup>2</sup>The word tuners is used for the free parameters of an optimization that are changed by the optimizer.

$d_c^+ \in \mathbb{R}^{n_c}$  and is calculated using eq. (12).

$$d_c^+ = \frac{d_c}{\int_0^{t_f} \left( \sum_{i=1}^{n_c} d_{c,i} N_{i,n_s}(t) \right) dt} \quad (12a)$$

$$\Rightarrow s(t_f) = \int_0^{t_f} \left( \sum_{i=1}^{n_c} d_{c,i}^+ N_{i,n_s}(t) \right) dt = 1 \quad (12b)$$

This reshaping leads directly to  $s(t_f) = 1$  so that the optimizer does not have to fulfill the equality condition by itself. For time optimal optimizations  $t_f$  is also a tuner and the discrete B-spline control points  $t_i$  are reshaped to lie in the interval  $[0, t_f]$  if  $t_f$  is modified by the optimization algorithm.

## 5.1 Trajectory optimization results

Trajectory optimizations on the basis of an inverse satellite model were performed for a reorientation maneuver of  $28^\circ$  around the axis  $e_{rot} = (1, 1, 1)^T$ .

Figure 6: Motor currents for the energy optimal control function.

Figure 7: Energy optimal control function for fixed  $t_f$ .

All optimization are performed using a B-spline parameterization of the control function with  $d_c \in \mathbb{R}^{30}$  as described in the last section. Starting values are found

Figure 8: Motor currents for the time optimal control function.

Figure 9: Time optimal control function.

using a global genetic algorithm with a population size of 100 and a rigid inverse satellite model. After good initial parameters have been found, the parameters are refined using a local pattern search algorithm [14, 27] with a complete approximate structural elastic inverse satellite model as described in sec. 3 (including flexible powertrains and flexible solar panels). For both optimization steps the reshaping of the tuners was used as described in the last section.

The first optimization was performed for a fixed end-time  $t_f = 10s$ . It was the goal to minimize the required energy of this maneuver, according to the criteria given in eq. (10) with  $\xi_t = 0$  and  $\xi_f = 1$ . The plots in fig. 6 and fig. 8 show the resulting optimized motor currents and the corresponding control functions as shown in fig. 9 and fig. 7. The second optimization was performed for the parameters  $\xi_t = 1$  and  $\xi_f = 0$  in eq. (10) with free end time  $t_f$  (as tuner) and results in a time optimal solution for the given path. The resulting trajectories allow to reorient the satellite according to the desired SLERP path. Although there are still oscillations of the flexible components (e. g. solar panels), they are compensated by the reaction wheels

such that the ACS-frame follows the desired path. In addition, limitations on the motor currents and motor velocities are maintained. Small errors that result from the approximations used for the generation of the inverse model can be compensated by a feedback controller (in addition to modeling errors in the case of a real satellite).

## 6 Conclusion

In this paper, we have presented the Space Systems Library which provides components for satellite/spacecraft nonlinear modeling in Low Earth environment. We demonstrated the library capabilities with a new method for model-based attitude control of a satellite with flexible solar panels.

The method consists on transferring the inverse flexible model approach, successfully implemented in the field of industrial robotics, to the application of flexible satellites modeling and control.

The inverse satellite model allows the computation of the motor currents for a given trajectory of the satellite in a way that the elasticity of the powertrains and flexible solar panels is taken into account and compensated. Using the inverse model, optimal re-orientation maneuvers have been computed for energy and time optimality. The use of inverse satellite models in this optimization greatly improves the optimization process by simplifying the problem considerably.

As part of a two degree of freedom control system, the inverse satellite model can be used as a feed-forward controller to compensate elastic effects and other modeled nonlinear effects that act on the satellite.

## Abstract

Stage separation dynamics modeling is a critical capability of future launchers preparatory studies. The development of stage separation frameworks integrable in end-to-end launch vehicle trajectory simulations have been presented in the relevant literature but none profiting from the object-oriented and equation-based acausal modeling properties of MODELICA. The objective of this paper is therefore to present such an approach to this problematic. Based on the *Constraint Force Equation* (CFE) methodology, two case studies to evaluate the proposed approach are considered. Results demonstrate that the approach corresponds very well with the physics behind separation. In addition, we found easiness of implementation of the method within a single environment such as DYMOLA, demonstrating the benefits of an integrated approach.

## 1 Introduction
